Except for the demonstration of auto-agglutinins, the laboratory findings resemble those described earlier. The agglutinins may be active in the cold (4° C.), but often show a wide thermal amplitude, being demonstrable at 37° C. They are usually pan-agglutinins for human erythrocytes, but unlike the naturally occurring cold agglutinins with anti-A, anti-B, anti-O, anti-M, anti-N or anti-P specificity, may rarely be selective of human blood groups, especially of Rh subtypes. The auto-agglutinins must be differentiated from the foregoing specific agglutinins and from the naturally occurring cold panagglutinins which many normal persons have in their serum in low titer. The titer of abnormal agglutinins is usually high, and they have the property of coating the patient's erythrocytes and almost always producing a positive direct antiglobulin test (Coombs' test). They may also be demonstrated by the indirect antiglobulin technique

and by the technique of trypsin digestion, using erythrocytes of a normal person.

The coating antibodies render the erythrocytes of the patient susceptible to spontaneous agglutination, particularly in normal serum or albumin solution or on glass surfaces at room or body temperature. This effect may seriously interfere with accurate typing of the patient's blood and with the cross-matching procedure. For example, if the patient is erroneously typed AB, no AB blood will be compatible, or, if the patient is correctly typed, blood which is compatible will not be satisfactory in the cross-matching procedure. These difficulties can sometimes be circumvented by washing the patient's cells several times with warm saline solution (37° C.) and by performing all tests at 37° C., using prewarmed reagents, except that the serum of the patient is separated from the clot and warmed only after it has been incubated with the clot at 4° C. for at least an hour or preferably overnight. These precautions tend to secure reagents as free of interfering substances as possible and to permit the cold agglutinins as little activity as possible. If satisfactory results cannot be obtained after cross-matching with as many group O bloods as possible, group O Rh-negative blood may be cautiously used for the transfusion of these patients. A or B blood group substances should be added if the patient is not group O.

Acquired hemolytic anemias associated with auto-agglutinins are usually acute and self-limited. They may need transfusion therapy, but this should be used sparingly, perhaps only when the hemoglobin level is under 5 gm. per 100 ml. Occasionally these anemias become subacute or chronic. Administration of ACTH or cortisone may be effective, and splenectomy may be so in about half of the chronic cases. These measures may suppress the hemolytic process or induce temporary or lasting remissions. With either treatment the production of auto-agglutinins and the positive Coombs' test may persist for months or years, while the hemolytic process remains quiescent.

#### HEMOLYTIC REACTIONS DUE TO TRANSFUSION OF INCOMPATIBLE BLOOD

Hemolytic transfusion reactions may occur as a result of infusion of erythrocytes into a patient who has iso-agglutinins specific for these erythrocytes or as a result of the infusion of plasma containing iso-immune bodies for the recipient's erythrocytes. The most important reactions involve hemolysis

of the donor's cells rather than of the recipient's; at times erythrocytes of both donor and recipient are destroyed (for example, when group A blood is given to a group B recipient).

The safeguards of blood transfusion are outlined elsewhere (p. 200). The *treatment*

of the hemolytic reaction is mainly directed at control of *acute renal injury* (p. 1050).

#### HEMOLYTIC DISEASE OF THE NEWBORN (ERYTHROBLASTOSIS FETALIS)

The term *hemolytic disease of the newborn* includes a number of hemolytic processes

Peripheral Blood

Bone Marrow

**FIG. 305.** Morphologic alterations in erythrocytes in hereditary hemolytic anemias. In *A* the small, dark-staining spherocytes of hereditary spherocytosis are seen. Large polychromatophilic erythrocytes are also present. There is erythroid hyperplasia in the marrow specimen. In *B* the hypochromia, anisocytosis and poikilocytosis characteristic of thalassemia major are evident. The marrow shows corresponding variability in the cytoplasm of normoblasts, which are greatly increased in number. In *C* sickle cells are present, with erythroid hyperplasia in the marrow. In *D* the striking degree of target cell formation is seen as a manifestation of hemoglobin C-sickle cell disease. This chronic hemolytic anemia is accompanied by erythroid hyperplasia in the marrow.

occurring in the fetus and in the newborn infant. The most important of these is hemolytic disease due to iso-immunization with respect to the Rh factor; next in importance is hemolytic disease due to A or B iso-immunization. Hemolytic disease may occur occasionally as a result of hereditary spherocytosis or other conditions uncommon at this age. Hemolytic disease of the newborn due to Rh iso-immunization has long been known as *erythroblastosis fetalis*; this is an unsatisfactory term because it focuses attention on an aspect of illness which is neither specific nor always present in Rh incompatibility. It seems preferable to designate the various hemolytic conditions occurring in the neonatal period as *hemolytic disease of the newborn*, and then in each instance to identify additionally the category of the hemolytic disturbance.

Hemolytic disease of the fetus or newborn infant is generally due to an isohemagglutinin in maternal serum. The antibody produces agglutination *in vitro* of the red blood cells of the infant and of the father and identifies a factor in their erythrocytes which is lacking in the mother. Typically, Rh iso-immunization affecting the fetus is based upon (1) stimulation of an Rh-negative mother by the Rh-positive red cells of the fetus, or on occasion by transfusion or injection of other Rh-positive blood cells; (2) production by her of an anti-Rh agglutinin; (3) passage of this substance across the placenta into the circulation of the infant; and (4) destruction of fetal erythrocytes by specific reaction with the anti-Rh agglutinin. A similar train of events can result when the father and mother have an incompatibility in the ABO system. Clinical manifestations of hemolytic disease are, in fact, more commonly due to incompatibility of a group A or group B fetus with its mother than to Rh incompatibility. A or B iso-immune disease in the newborn is usually mild, however, and most often overlooked. Hemolytic disease may also be caused by incompatibility with respect to other antigens (Rh-Hr system) related to the original Rh antigen (D) or by incompatibilities within other blood groups such as Kell-Cellano (K-k) or the MNS group (factors S and s).

#### HEMOLYTIC DISEASE DUE TO RH INCOMPATIBILITY

**Genetics and Pathogenesis of Rh Sensitization.** Severe hemolytic disease is most often due to Rh or related incompatibilities.

Rh antigens may be regarded as associated with three linked pairs of genes, designated C and c, D and d, and E and e. Each gene determines a red blood cell antigen which has the same identification. The D antigen is responsible for most cases of hemolytic disease, and it is considered practical to regard the terms "Rh positive" and "Rh negative" as meaning "D positive" and "D negative," respectively. The offspring of a D-positive father and a D-negative mother will be D positive in all cases if the father is homozygous; i.e., if he has two D genes and is, therefore, DD. If the father is heterozygous, i.e., if he has only one D gene and is, therefore, Dd, each of his children has a 50 per cent chance of being D positive. Approximately 15 per cent of white persons are Rh negative, about 38 per cent are Rh positive homozygous, and about 47 per cent are Rh positive heterozygous.

Two conditions are prerequisite to the development of Rh antibodies in the Rh-negative mother: (1) Rh antigen (fetal or blood donor) must enter the maternal circulation; (2) the mother must be capable of producing the specific agglutinins. The transfer of small numbers of fetal cells across the placenta into the maternal blood undoubtedly occurs in all pregnancies. The most important initial sensitization in the mother may come, however, at the time of delivery of her first Rh-positive infant and placenta. A mother who is able to produce antibodies easily will likely do so in response to this stimulus, so that the first affected infant of the easily sensitized mother is likely to be her *second* Rh-positive infant. A miscarriage of the first pregnancy may also sensitize the mother. When antibody production is not excited by the first Rh-positive infant, the Rh-negative mother may respond to subsequent pregnancies. Instances are known, however, when twenty or more Rh-positive fetuses did not produce sensitization of an Rh-negative mother. There is evidence that a mother not easily sensitized may produce antibodies of low titer or pathogenicity, and that the affected infant will likely have a mild disease.

Transfusion of the Rh-negative woman with Rh-positive blood is a potent stimulus to sensitization. About half of all Rh-negative recipients of a single Rh-positive blood transfusion will produce Rh antibodies; multiple transfusions will sensitize 90 per cent or more of recipients. Hemolytic disease in the first-born Rh-positive infant of an Rh-negative

mother (5 to 10 per cent of cases) is most often the result of previous sensitization by blood transfusion or intramuscular injections of blood.

Besides the mother's exposure to antigen and her capacity for reactivity, other factors tend to limit the occurrence of hemolytic disease. Thus, when the husband of the Rh-negative woman is incompatible with her in the AB system as well as the Rh one, her sensitization to the Rh factor is less likely than if he is compatible with respect to A and B. Most Rh-positive men are heterozygous with respect to D, so that only half of their infants are antigenic in this respect to the mother. These factors and the tendency toward small families limit the occurrence of hemolytic disease in the Rh system to about one in every 200 births, whereas about 12 per cent of marriages in this country are of Rh-negative women with Rh-positive men.

**Pathology.** The pathologic changes are those of an acquired hemolytic anemia, but certain additional features related to the occurrence in fetal life and in the neonatal period are more or less peculiar and account for the designation erythroblastosis fetalis. There may be no abnormality in mildly affected infants, or there may be alterations which vary from mild splenomegaly to severe hepatosplenomegaly with extensive extramedullary erythropoiesis in liver, spleen, heart, skin and other tissues. Nucleated erythrocytes may be prominent in blood sinuses and vessels, and deposition of iron pigment may be widespread. In severely affected infants there may also be cardiac enlargement, hyperplasia of the islands of Langerhans, lipid infiltration of adrenals and atrophy of lymphatic tissue. Local accumulations of fluid may occur in serous cavities, or there may be generalized edema (hydrops fetalis, universal edema of the newborn), which is thought to be due to anemic cardiac failure, but may also be secondary to or aggravated by hypoproteinemia or anoxic shock. Hydrops fetalis is usually fatal before or just after delivery. The placenta of the hydropic infant is also edematous, large, friable and pale. Hydropic degeneration of the villi is seen microscopically.

These pathologic changes conspicuous in infants dead or dying at birth are found in varying degree in infants who die of hemolytic disease *after the first day of life*, in whom the most characteristic finding is *kernicterus*, or jaundice of the nuclear masses of

the brain in association with severe generalized icterus. This lesion may be seen only grossly, as faint to marked yellow pigmentation of the basal ganglia, amygdala, inferior olive, dentate nucleus of the cerebellum, vegetative centers of the medulla, or gray matter of the spinal cord. Kernicterus may be seen on the surface of the brain in the mammillary bodies, in the flocculi of the cerebellum and on the hippocampal gyrus. There is good evidence that the pigment is indirect-reacting bilirubin.

Microscopic changes of acute kernicterus are variable. Necrobiosis and pigment-laden ganglion cells are seen at times, but often there are no microscopic abnormalities. Some infants with clinical signs of kernicterus survive many weeks or years. In those whose brains have been examined as short a time as a few weeks after the neonatal period the presumed yellow stain is no longer present. There may, however, be gliosis in the areas thought to have been stained.

Kernicterus, which almost never occurs in infants not surviving at least thirty-six hours, is closely related to the degree of immaturity of the infant, the level of maternal antibody, the sex of the infant (more boys are affected) and the level of serum bilirubin attained within the first week of life.

Infants with a severe hemolytic component who live several days or weeks may have plugging of bile canaliculi and changes suggestive of early portal fibrosis.

**Clinical Manifestations.** About 15 to 20 per cent of Rh-positive infants of sensitized Rh-negative mothers have no clinical illness. Of those who do, the manifestations are largely the results of hemolysis. Jaundice is rarely manifest at the moment of birth, but may become evident within a few minutes or hours. The vernix may be normal in appearance or dark yellow, and may give a golden yellow appearance to a severely ill infant whose skin is not icteric. Anemia of some degree is generally present initially or within the first few days of life, and the peripheral blood usually contains immature cells, chiefly of the red cell series. Universal edema and general anasarca (hydrops fetalis) are usually found only in stillborn infants or in those dying shortly after delivery. The placenta is often normal or may be considerably enlarged with characteristic microscopic changes.

Increasing icterus often masks developing pallor, which may increase rapidly after the third day of life. The liver and spleen may

be moderately or greatly enlarged at birth, or may become palpable during the first week of life. Enlargement of the heart and hemic murmurs are common in severely anemic infants. Petechiae and a bleeding tendency occasionally occur in the first day or two.

Kernicterus (p. 1077), when manifest, usually appears between the second and sixth days of life. The signs are increasing lethargy, poor feeding, and loss of the normal Moro response. There may be spasms of rigidity and opisthotonos, during which the infant assumes a characteristic posture with arms stiffly extended and inwardly rotated, and fists clenched. These spasms are particularly likely to result from handling and are often accompanied by a sharp, high-pitched cry.

Most infants with kernicterus due to Rh incompatibility die within the first week, usually with the clinical findings of pulmonary hemorrhage. If they survive the newborn period, they almost always show evidence of extrapyramidal motor difficulties and usually mental retardation. Impairment of hearing is common. Kernicterus occurs predominantly in infants who are severely jaundiced, especially if they are premature by as little as a week or two, and has *no* close relationship to other aspects of the hemolytic process.

**Laboratory Data.** In subclinical illness no abnormality other than a positive Coombs' test (see p. 201) may be found to suggest a hemolytic process. In many instances, however, an outstanding characteristic is an excess number of nucleated erythrocytes in the peripheral blood in the first day or two of life (from the usual 200 to 2000 nucleated red cells to 10,000 to 100,000 per cubic millimeter). There may also be increased numbers of reticulocytes, red cells with nuclear fragments, and macrocytic erythrocytes well filled with hemoglobin. The anemia may be slight or severe in the first twelve hours of life and, as the disease progresses, may worsen rapidly. A profound anemia may ensue by the end of the first or second week in a child not anemic at birth. The nucleated erythrocytes tend to diminish and may even disappear by three to four days; their absence should not confuse the diagnosis.

The erythrocytes may show slight increases or decreases in osmotic fragility. Spherocytes are not common; erythrophagocytosis is frequently demonstrated.

The leukocytes vary from 15,000 to 30,000 per cubic millimeter, with immature forms of granulocytes and lymphocytes predominant. In unusually severe cases a leuke-

moid picture may be found, and the platelets may be reduced in number in the first few days. The bleeding time may, therefore, be prolonged, and a prothrombin deficiency may augment the bleeding tendency. After the first few days the platelets return to normal levels, and the bleeding tendency subsides.

In spite of the absence of jaundice at birth there is often an elevation of serum bilirubin above 3 mg. per 100 ml. in blood of the umbilical cord. In severely affected infants the level of bilirubin may rise at a rate of 1 mg. per 100 ml. per hour for the first three to four days unless treatment is instituted. The pigment is ordinarily almost entirely of the indirectly acting form, but in severely affected infants a substantial portion (up to 50 per cent) may give a direct reaction.

Between the first and fourth weeks of life it is not unusual for the feces to become clay-colored and the urine bile-tinged. This acholic state (the so-called *inspissated bile syndrome*) lasts only a few days or weeks. During the period of active hemolysis both the urine and the feces contain increased amounts of urobilinogen.

It is usually not possible to demonstrate the anti-Rh (anti-D) agglutinins in the mother's serum when the infant's Rh-positive cells are suspended in saline solution; cellular suspensions in several dilutions may be necessary in one of several colloidal media. Appropriate media are *adult* human serum (group AB), 20 per cent bovine albumin, combinations of the two, or certain other substances. Occasionally there will be interference by prozones in the serial titration of maternal serum in these media. Digestion of the Rh-positive erythrocytes by trypsin tends to circumvent this prozone activity; properly digested cells will agglutinate with virtually all anti-Rh antisera, even in saline solution. The slide agglutination test of Diamond and Abelson is another method of value in the demonstration of abnormal Rh agglutinins and detects most prozones. The antiglobulin technique ("indirect" Coombs' test) is the most sensitive method for detecting anti-Rh antibodies and prozone activity. No test for maternal anti-Rh activity is infallible; therefore no serum should be regarded as negative in a suspected case unless all possible tests using as many different reagents as possible (at least two different antiglobulin sera) have been repeatedly negative.

It is as important to show that the infant

is Rh positive as to show that the mother has anti-Rh agglutinins. This is usually not difficult by ordinary techniques, but occasionally the Rh-positive red blood cells of an affected infant are coated with anti-Rh antibody ("blocking antibody" or "incomplete agglutinin"), which prohibits their agglutination with anti-Rh serums in ordinary tests. Its presence can be demonstrated by the "direct" antiglobulin test, which is usually positive even in those infants who will have no clinical disease.

It is frequently possible to demonstrate anti-Rh agglutinins in the serums of affected infants, but only in serum or albumin media. The Rh-negative offspring of mothers who have incomplete anti-Rh agglutinins will also have such antibodies in their serums for a few weeks after birth in approximately the same titer as in the mother's serum. Their presence is not associated with illness, but transfusion of Rh-positive blood should, as always, be avoided.

**Diagnosis.** The definitive diagnosis of hemolytic disease of the newborn rests upon the *demonstration of an abnormal maternal agglutinin which has specific activity for the erythrocytes of the fetus or infant*. The tentative diagnosis should be made *before* the birth of the infant through demonstration of anti-Rh antibody in the blood of the Rh-negative mother; the diagnosis is confirmed when the newborn infant is shown to be Rh positive. There are no other clinical or laboratory tests which can make or exclude the diagnosis with confidence, since some affected infants destined to have severe illness appear normal at birth, and since the changes usually associated with hemolytic disease may be those of another process.

When antenatal study is inadequate, the diagnosis of hemolytic disease due to Rh incompatibility is suggested whenever conspicuous icterus occurs within the first thirty-six hours of life. If, in such circumstances, incompatibility in the Rh group can be excluded by laboratory tests, A or B incompatibility will likely be demonstrable or, rarely, hereditary spherocytosis.

Toxoplasmosis, cytomegalic inclusion disease, sepsis, congenital syphilis, thrombocytopenic purpura or congenital leukemia may occasionally resemble hemolytic disease clinically. Infants of diabetic or prediabetic mothers may occasionally have normoblastemia and hepatomegaly and perhaps other suggestive signs, but the hemolytic element is usually minimal or absent. A severe anemia in a new-

born infant, with no signs of hemolysis, may occur if fetal blood has been lost through retroplacental hemorrhage in abruptio placentae or during the second stage of labor.

**Course and Prognosis.** Hemolytic disease may result in (1) stillbirth, with or without hydrops fetalis; (2) death, as a rule within twenty-four hours after delivery, from overwhelming anemia, usually with hepatosplenomegaly, often with edema, but rarely with evidence of kernicterus; (3) death, usually after the first day and before the sixth day, from kernicterus and pulmonary hemorrhages; (4) survival, with kernicterus manifest in residual central nervous system damage; (5) recovery from an illness of mild to great severity, in which the pressing therapeutic problems, if any, will be either anemia or hyperbilirubinemia; or (6) spontaneous recovery, without clinical manifestation of illness.

If an infant with hemolytic disease survives the first week of life without development of signs of kernicterus, the prognosis is favorable, provided the development of severe anemia is carefully watched for and treated. After the first week of life the hemolytic tendency diminishes, but the bone marrow enters an aregenerative phase which may last four to six weeks. Improvement is signalled by a fairly marked reticulocytosis. Normal hemoglobin and erythrocyte levels are usually attained by the fifth month, and thereafter there are no sequels related to the anemia.

The prognosis of hemolytic disease in the first infant born after maternal sensitization is in general favorable. About 5 to 10 per cent of the first affected infants will be stillborn, but over 90 per cent of the remainder will recover with adequate treatment. When there is a history of a previously affected offspring, the prognosis for subsequent Rh-positive infants is somewhat less good; more will have clinical illness; the case fatality rate will be higher; and the stillborn rate will increase to 30 per cent. Often, but not invariably, the pattern in a given family is that of a nearly uniform degree of illness in the involved infants, which may be mild or severe.

Premature birth, even as little as two weeks, carries a high risk of kernicterus in affected infants. The incidence of kernicterus in spontaneously delivered affected infants treated only for anemia is about 5 to 15 per cent. The incidence can be reduced to less than 1 per cent by adequate exchange trans-

fusions or may be raised to 30 per cent or more by premature induction of labor when multiple exchange transfusions are not performed. The likelihood of kernicterus is closely related to the level of serum bilirubin; it rarely occurs when serum levels do not exceed 20 mg. per 100 ml.

**Treatment.** Management of the newborn infant with hemolytic disease properly begins with its *anticipation* through routine typing of every woman in each pregnancy and performance of at least one test for Rh antibody within four weeks of delivery of every Rh-negative woman. If no maternal anti-Rh antibody is detected at or after thirty-six weeks of gestation, no illness is to be expected in the infant. If antibody is found, irrespective of its titer, a potentially sick infant should be prepared for. Such preparation should include examination of the infant *at the moment of birth* for evidence of need for immediate treatment.

No method is known to alter favorably the sensitization of the mother prenatally, nor to increase the resistance of the infant to her antibodies. Cortisone has been used in pregnant, sensitized women and in affected infants, and ACTH in the latter; the results of such therapy have been disappointing in mothers and inconclusive in infants. There is no evidence that an Rh hapten has therapeutic properties.

The likelihood of stillbirth is to a great extent related to the titer of antibody in the mother, but irrespective of the titer the probability of stillbirth is high in the offspring of a mother who has had a previously stillborn infant as a result of hemolytic disease. Chown and Allen have shown that if stillbirth is to be prevented in a substantial number of infants of such mothers, then birth may need to be induced before term. Chown reports improved results when the delivery is as early as thirty-two to thirty-four weeks and the infant is treated by multiple exchange transfusions. Allen, however, has had unfavorable results in infants delivered by cesarean section at such an early date and recommends that the infant in such cases be delivered at thirty-seven weeks' gestation or as soon thereafter as medical induction of labor seems possible. When early delivery is contemplated in a mother who has had a previous stillbirth, any subjective sign of impending fetal death may be one of the best indications for immediate delivery.

Such early delivery adds the increased risk of kernicterus to the normal hazards of

prematurity. Within the past few years, however, it has become apparent that kernicterus can be prevented even in premature infants by *multiple* exchange transfusions. It is not to be inferred that multiple exchange transfusions offer easy control; hyperbilirubinemia may be controlled only with great difficulty in such infants, if at all, and as many as six or more exchange transfusions may be necessary.

The delivery of the potentially affected infant should be managed with as little sedation or anesthesia as possible, and the Rh type of the cord blood should be obtained immediately after delivery.

If the potentially affected infant *appears* by direct typing to be Rh negative, a direct antiglobulin test (Coombs') must be carried out to exclude the possibility that the infant is Rh positive with coated cells. If both tests are negative, *and if there are no clinical signs of hemolytic disease*, the infant may be considered Rh negative and free of illness.

If the infant is Rh positive and has clinical signs of illness, an *exchange transfusion with Rh-negative blood* should be carried out as soon as possible. An exchange transfusion should be carried out if there are no signs of clinical illness, if the maternal titer of anti-Rh antibodies is 1:64 or more, if the infant is two weeks or more premature or if there has been a previously affected infant with hemolytic disease of clinical severity requiring treatment, and especially if kernicterus has occurred. If none of these indications is present, the hemoglobin and bilirubin levels are determined *immediately* in the cord blood, and an exchange transfusion is carried out if the hemoglobin level is less than 14 gm. per 100 ml. or if the level of serum bilirubin is above 3.5 mg. per 100 ml.

If no indication for exchange transfusion exists at birth, the infant must be closely watched. If the infant becomes jaundiced within eight to twelve hours, or if the level of serum bilirubin exceeds 10 mg. per 100 ml. within the first twenty-four hours, an exchange transfusion is indicated. If, after an initial exchange transfusion, the level of serum bilirubin exceeds 18 mg. per 100 ml., a second exchange transfusion is indicated. Three or more exchange transfusions are occasionally necessary in severely affected or premature infants in order to keep the level of serum bilirubin within the safe range (below 20 mg. per 100 ml.).

It cannot be too strongly emphasized that adequate facilities must be available for mul-

multiple exchange transfusions in the hands of experienced personnel and for continuing and skillful nursing care. No hospital should accept responsibility for these infants which cannot provide on short notice an accurate determination of the level of serum bilirubin at any hour of the day or night.

The umbilical vein, which is usually available for at least five days, is the preferred channel for exchange transfusion. The infant is kept in a heated bassinet, and a polyethylene or polyvinyl cannula is placed in the umbilical vein under aseptic conditions. Small amounts (10 to 20 ml.) of the infant's blood and Rh-negative blood are withdrawn and injected, respectively, until about 500 ml. of blood have been exchanged. In some of the most severely ill infants there is an increase in venous pressure and in blood volume at birth; any further increase in blood volume may be very dangerous. When the venous pressure at the level of the umbilicus of the supine infant exceeds 8 to 10 cm. of saline solution, it may be advisable to carry out the exchange transfusion so that the infant's blood volume is decreased by as much as 50 to 100 ml., if his blood cell count is restored to normal. This situation is unlikely when the infant's clinical condition is good or when additional transfusions are required after the initial one.

Blood for exchange transfusions should be as fresh as possible and in no instance stored longer than four days, since there may be dangerous increases in plasma levels of potassium. *The blood should always be compatible with the mother's serum by the indirect antiglobulin technique* (Coombs' test). If this requires that group O blood be given to a group A or group B infant, A or B group-specific substance may be added. Blood is best given at body temperature and should not be exposed to higher temperatures after removal from the refrigerator.

Infants with hemolytic disease who do not require exchange transfusions should be watched carefully for at least three weeks for the development of anemia, even when they appear to have no clinical illness. Determinations of hemoglobin levels daily during the first week and twice a week for the next two weeks will usually suffice to determine an anemia requiring treatment. A fall in hemoglobin level below 9 gm. per 100 ml. within the first two weeks of life can usually be considered an indication for a small transfusion of sedimented erythrocytes. After three weeks of age a somewhat lower level of hemoglobin

can be tolerated, since the aregenerative phase of this disease ends at five to six weeks. At this time a reticulocyte response occurs, and the hemoglobin level, which may now be 7 to 7.5 gm. per 100 ml., begins to rise. Transfusion is not ordinarily necessary between three and six weeks of age unless the level of hemoglobin is below 7 gm. The infant does not need iron or other antianemic substances. Infants who have received exchange transfusions rarely need additional transfusions for anemia.

Although anti-Rh agglutinins may be demonstrated in the milk of mothers who have appreciable titers of these agglutinins in their serums, they are not a contraindication to breast feeding. It is doubtful whether ingested agglutinins significantly affect circulating erythrocytes.

#### HEMOLYTIC DISEASE DUE TO A OR B INCOMPATIBILITY

Relatively mild hemolytic disease associated with A or B incompatibility appears to be at least as common as clinical Rh incompatibility, but usually escapes attention because it is rarely accompanied by significant anemia, and extremely rarely by hydrops fetalis. The main clinical manifestation is jaundice ("icterus praecox"), which usually has its onset within the first thirty-six hours of life. Hepatosplenomegaly is mild or absent. Kernicterus occurs with some frequency (perhaps 5 per cent) and may be more common with B incompatibility than with A. The first-born is affected as often as subsequent infants.

There is usually little or no anemia, but there may be spherocytosis and pronounced reticulocytosis. The leukocytes and platelets show no distinctive changes. The direct antiglobulin test (Coombs' test) is usually negative, but may be weakly positive. The coated cells of the infant are usually susceptible to spontaneous agglutination in adult serum (group AB) or in certain other media (glues). Anti-A or anti-B in maternal serum is easily demonstrable as an agglutinin in saline solution and may act as a hemolysin against appropriate cells. The *titer* of ordinary (saline-active) anti-A or anti-B agglutinins may be high or within the normal range, but has no diagnostic or prognostic significance. Witebsky has shown, however, that in nearly all cases of clinical A or B incompatibility other A or B antibodies are generally present which remain active in adult serum or in certain other media after

the saline-active agglutinin has been neutralized by its group-specific polysaccharide. These are the so-called immune anti-A or anti-B antibodies. They may at times be demonstrated, after neutralization, by using *adult* erythrocytes of group A or B digested by trypsin or by the indirect antiglobulin technique, using adult cells.

Hemolytic disease due to A or B incompatibility is not commonly anticipated antenatally unless a previous infant in the family has been affected. Attention is usually called to the affected infant by the early onset of icterus. Laboratory examination of the infant's and the mother's blood will establish whether potential incompatibility exists, and, if so, with respect to what blood antigen. Unanticipated Rh incompatibility and icterus neonatorum will most often need to be differentiated. Rarely, hereditary spherocytosis will simulate hemolytic disease due to A or B incompatibility and may be especially difficult

to distinguish if coincidental A or B incompatibility exists.

Because in all these conditions kernicterus may be associated with a high level of bilirubin, the observation of jaundice in a newborn infant should always be considered an indication for critical appraisal; if he is less than thirty-six hours old, it should be considered a pediatric emergency.

*Treatment* of A or B incompatibility is aimed solely at prevention of kernicterus. The level of serum bilirubin is probably the most effective guide to treatment. Exchange transfusion is done as necessary to keep the bilirubin level below 20 mg. per 100 ml. Group O blood of appropriate Rh type is used. A or B substance may be added, so that the additional anti-A or anti-B in the blood of the donor will aggravate the condition as little as possible, but it may be more important to show that the donor blood does not have "immune" anti-A or anti-B agglutinins.

## POLYCYTHEMIA, ERYTHROCYTOSIS AND ERYTHREMIA

The term "polycythemia" designates a higher than normal level of circulating erythrocytes and hemoglobin. Polycythemia is unusual in children, but may arise as a result of many different conditions.

Since the arterial oxygen content is a controlling factor in the production of hemoglobin and of erythrocytes, many conditions associated with reduced oxygen content of arterial blood will lead to a compensatory increase in the number of erythrocytes released from bone marrow. This *true* increase in numbers of circulating red blood cells is spoken of as *erythrocytosis*. By contrast, severe loss of fluid from the vascular compartment may result in a *relative* polycythemia. Such losses of fluid may occur with persistent vomiting or diarrhea, profuse sweating, burns or adrenal cortical insufficiency.

In cyanotic congenital heart disease erythrocytosis occurs as a result of decreased arterial oxygen content and may reach extreme degrees. Erythrocytosis rarely occurs in acquired heart disease, but may be seen in severe mitral stenosis when the diffusion of oxygen across thickened alveolar membranes is impaired. Other chronic pulmonary conditions which may be associated with compensatory erythrocytosis are emphysema, silicosis, cavernous hemangiomas, arteriovenous fistulas and neoplasms.

Chronic mountain sickness (*Monge's dis-*

*ease*), which occurs in persons living at high altitudes, is characterized by a striking erythrocytosis, headache, paresthesias, lethargy, and severe pain in the extremities. The illness abates in an environment of higher oxygen content.

Cushing's syndrome and certain brain tumors for some unknown reason may be associated with erythrocytosis, which is relieved upon correction of the primary process.

Prolonged erythrocytosis is accompanied by an increased demand for nutrients necessary for the production of erythrocytes and hemoglobin. An iron deficiency anemia may be present paradoxically even when the hemoglobin level is 16 to 18 gm. per 100 ml., as in children with cyanotic congenital heart disease. The judicious administration of iron is indicated in such instances. The hypochromia associated with erythrocytosis in thalassemia minor is *not* due to iron deficiency and should *not* be treated with iron.

*Erythremia*, or *polycythemia vera*, is characterized by overactivity of erythroid precursors in bone marrow in response to an unknown stimulus, which leads to an absolute increase in the circulating erythrocytes and usually in platelets. The disease is extremely rare in children. Clinical features in children resemble those in adults. A few instances of familial erythremia have been recorded.

## DISORDERS OF THE LEUKOCYTES

The peripheral blood contains leukocytes of three distinct types: granulocytes, lymphocytes and monocytes. All leukocytes are motile cells having characteristic ameboid activity. Each reacts in its own manner to various stimuli; all serve the body principally as agents of defense. Variations in their number and kind are significant indicators of the reaction of the body to many situations.

Recent studies indicate that three to five days elapse from the beginning of differentiation of the most immature precursor of the granulocyte to the delivery of a mature cell into circulating blood. The life span in the peripheral circulation is four to six days. The basophilic leukocyte and eosinophilic leukocyte have somewhat longer circulating spans: approximately seven to ten days.

The lymphocytes include two distinct kinds of cell with strikingly different life spans. A short-lived group has a mean span of three to four days; a larger group remains in the circulation 100 to 200 days. Abrupt changes in lymphocyte numbers, including such as may be induced by ACTH, generally involve the short-lived cells. The differences in life span of lymphocytes are not clearly related to differences in morphology.

Only a small fraction (estimated 1:400) of the total leukocyte population is in the circulation at one time. The reservoir of these important defense units is, therefore, ordinarily large.

The leukocytes contain zinc, vitamin C, thiamine, folic acid and alkaline phosphatase; alteration in cellular content of these materials is found in leukemia, and offers a field for further investigation.

**Granulocytes.** Granulocytes are produced in bone marrow. Both folic acid and vitamin B<sub>12</sub> seem to be necessary for their production. No other clearly defined nutritional requirement is known. Granulocytic leukocytes include the neutrophilic, eosinophilic and basophilic polymorphonuclear granulocytes.

The *neutrophilic* cells serve primarily as phagocytes, particularly in relation to pyogenic infections. When such infections occur, the number of neutrophilic cells in the blood is increased by mobilization from the marrow, and they accumulate in large numbers at the sites of acute inflammation, which they tend to localize. Other stress-provoking stimuli,

including vigorous exercise, may augment the production of neutrophils. Infants and children more readily deliver immature cells than do adults under similar stressful circumstances; myelocytes and even promyelocytes may be seen in peripheral blood. In severe infections or other toxic states the neutrophils may contain fine, deeply basophilic granules (toxic granules) or larger basophilic masses (Doehle bodies). Administration of ACTH and cortisone causes an increase in neutrophilic cells. Less common causes of neutrophilic leukocytosis in children include certain severe disturbances such as uremia, acidosis, burns, poisonings, infarctions and anoxia associated with hemorrhage or hemolysis. Malignant overproduction of neutrophils and their precursors occurs in myeloid leukemia.

In severe sepsis or extremely toxic states an unexpected leukopenia may indicate an inability to respond to a stressful situation (p. 964).

The functions of the *eosinophils* are poorly understood, but they seem closely related to immunologic mechanisms in the body, and are particularly involved in allergic conditions and reactions to invasion of tissue by parasites. The levels of eosinophils in the peripheral blood are strikingly related to the activity of the pituitary and adrenal cortical hormones. Under a variety of conditions of stress, or with the administration of these hormones, the number of eosinophils in peripheral blood shows a sharp decline. The disappearance of eosinophils from the peripheral blood in acute infections and other toxic states indicates the seriousness of the illness, and the reappearance of them often heralds clinical improvement.

The parasitic infestations associated with increase in eosinophils are predominantly those in which there is invasion of body tissues by parasites. Such diseases include trichinosis, echinococcus disease and infestation with *Toxocara canis* or *cati*.

Eosinophils are increased in a variety of allergic states and in certain hematologic disorders such as leukemia, pernicious anemia and Hodgkin's disease. Familial eosinophilia has been described.

*Basophils* occur in small numbers in the blood of children. Their function is unknown, and they appear to have clinical significance

only in that they are consistently elevated in chronic myelogenous leukemia in children.

**Lymphocytes.** Lymphocytes are produced by lymphoid tissue throughout the body, including the thymus, lymph nodes and bone marrow. Active production of lymphocytes is associated with hypertrophy of lymphoid tissue. These cells are closely related to processes in the body concerned with resistance and immunity to infection. The plasma cell is regarded as the probable source of the gamma globulin fraction of plasma proteins. ACTH and cortisone promote lysis of lymphoid tissue and of short-lived lymphocytes, presumably with release of immune bodies. The thymus and lymph nodes regress rapidly in size with treatment by these agents. In the event of decreased function of lymphocytes it might be expected that humoral immunity would be low. Agammaglobulinemia may represent a special form of defect in lymphocyte function.

Lymphocytes are likely to be found in association with chronic or subacute inflammatory processes, especially of a nonpyogenic variety. Like the eosinophil, they are increased in numbers in the convalescent phase of many infectious conditions.

*Relative* increases in the lymphocyte count may occur with many conditions when granulocytes are reduced in number. Such relative increases should be clearly differentiated from actual increases in numbers of circulating lymphocytes which may at times accompany such infections as mumps, German measles, tuberculosis, brucellosis and syphilis. Lymphocyte production is increased in a number of specific infections, such as pertussis, acute infectious lymphocytosis and infectious mononucleosis.

Malignant overproduction of lymphoid tissue occurs as lymphatic leukemia, lymphosarcoma and plasma cell leukemia.

**Monocytes.** The function of the monocyte is not known. An increase in their number is associated with such chronic bacterial infections as tuberculosis, typhus, brucellosis and subacute bacterial endocarditis, many protozoan infections and certain xanthomas and Hodgkin's disease. There is a marked monocytosis in monocytic leukemia.

**Leukopenia.** In certain overwhelming infections failure of production or mobilization of leukocytes with the occurrence of a leukopenic state is a grave prognostic sign. On the other hand, certain bacterial infections, such as typhoid and paratyphoid fevers, and many virus and rickettsial diseases

are characteristically accompanied by a leukopenia. The mechanism responsible for leukopenia under these circumstances is poorly understood, though a number of physical and chemical agents are known to depress leukopoiesis.

In a variety of conditions accompanied by splenomegaly (Gaucher's disease, Banti's syndrome, and so forth) the sequestration of large numbers of leukocytes in the spleen leads to leukopenia.

A leukopenia may also accompany severe malnutrition, and regularly accompanies the specific nutritional deficiencies of folic acid, vitamin B<sub>12</sub>, pantothenic acid, riboflavin and protein. Aplastic anemias are characteristically accompanied by inadequate production of white blood cells.

Glanzmann et al. have described three patients in whom a striking *lymphopenia* (*alymphocytosis*) was present with extensive infection of the alimentary tract and respiratory organs with *Monilia*. All three cases ended fatally.

In the early phases of anaphylactoid shock and after the intravenous administration of certain colloids as gelatin, globulin and fibrinogen, a reduction in the number of circulating lymphocytes appears to be due to their redistribution in the body. Leukopenia may also be associated with the production of antibodies against the white blood cells. The situation is analogous to that existing in thrombocytopenia, in which auto-immune bodies against platelets are found, or in acquired hemolytic anemia, in which there are auto-immune bodies against red blood cells.

## AGRANULOCYTOSIS

### (MALIGNANT NEUTROPENIA)

The term "agranulocytosis" is commonly used for a syndrome characterized by fever and acute necrotizing lesions of the pharynx associated with leukopenia and pronounced granulocytopenia, but without significant anemia or thrombocytopenia. Agranulocytosis may follow the administration of small amounts of certain coal tar derivatives, particularly amidopyrine. It has also been related to the administration of barbiturates, sulfonamides, dinitrophenol, thiouracil, trimethadione and Mesantoin. The fundamental process may be an allergic or hypersensitive state. The wide appreciation of the dangers of drugs causing agranulocytosis has led to a greatly lowered incidence of this disease.

**Clinical Manifestations.** Fatigue and

weakness are often the initial symptoms, which may then be followed by the sudden onset of a much more striking illness with chills, fever, severe prostration and irritability. Within a few hours, or a day or two, the more characteristic features of agranulocytosis develop; these are extensive necrotic and ulcerative lesions in the skin, the oral cavity, gastrointestinal tract, vagina or uterus. The tissues of the mouth and pharynx are the ones commonly involved. Mental confusion may develop, and coma soon follows; the severely involved patient may die within three to five days. Antibacterial therapy may alter the course of this devastating illness and permit recovery.

**Laboratory Data.** The total leukocyte count is depressed and is usually in the range of 1000 to 4000 cells per cubic millimeter. The leukocytes present are principally lymphocytes, with many basophilic forms. Anemia and thrombocytopenia are not present. Bacteriologic cultures of the blood and of the areas of local infection will usually reveal pathogenic organisms.

The bone marrow reveals a reduction in granulocyte precursors, especially the more mature ones, with normal erythropoiesis and normal numbers of megakaryocytes.

**Diagnosis.** Careful inquiry about the ingestion of an agent known to be causative of agranulocytosis is of utmost importance. Aplastic anemias are accompanied by thrombocytopenia and anemia. The combination of lymphadenopathy, splenomegaly, thrombocytopenia, anemia and the presence of immature leukocytes in the peripheral blood will suggest acute leukemia; examination of bone marrow may be diagnostic. In infants and children with overwhelming sepsis, leukopenia and granulocytopenia may be difficult to differentiate from agranulocytosis.

**Course and Prognosis.** Untreated, acute agranulocytosis ordinarily runs a rapidly fatal course. Chronic forms of agranulocytosis have been observed, however, which follow a protracted course. Mortality rates have been reduced from previous rates of 75 to 90 per cent by appropriate antibiotic therapy and other supportive measures.

Patients who have agranulocytosis from therapy with a particular drug are likely to get the disease again if the causative agent is ingested later.

**Treatment.** Appropriate treatment of the infection with antibiotic drugs is the prime factor in the therapy of agranulocytosis. Direct attempts to stimulate production of

granulocytes in bone marrow have met with failure. Transfusions of whole blood are of little value. Adrenal steroids and ACTH are of doubtful benefit.

## PERIODIC NEUTROPENIA

### (CYCLIC NEUTROPENIA)

Periodic neutropenia is a rare disease of unknown cause characterized by regularly recurring episodes of neutropenia. The onset is usually in infancy or childhood, although some affected persons have not been detected until old age. Symptoms are related to infection, which may take the form of stomatitis, conjunctivitis, furunculosis, or localized abscesses of the skin. Lymphadenopathy, fatigability and fever are often associated. The neutropenia recurring at intervals of about three weeks and lasting four to seven days is often associated with infection. Agammaglobulinemia is suggested, and Good has observed the two conditions in the same patient. Hypergammaglobulinemia accompanying the neutropenia, but fluctuating independently of it, has also been observed.

The erythrocyte count and blood platelets are not affected. The leukocyte count usually falls to 4000 or less per cubic millimeter and the percentage of neutrophilic leukocytes to less than 15 per cent during the period of neutropenia. The bone marrow, which is normal between episodes, shows failure of maturation of leukocytes beyond the early metamyelocyte stage during the neutropenic phase.

*Treatment* is nonspecific and supportive. The infection can often be controlled by prophylactic antibiotic therapy as the period of neutropenia approaches. The neutropenia has been prevented in some patients by administration of ACTH. Splenectomy is reported to have been beneficial.

## CHEDIAK-HIGASHI SYNDROME

An increasing number of infants are being found who have an abnormality of granulocytes first described by Chediak in 1952. The condition is genetically transmitted, probably as a recessive trait. The abnormality of granulocytes is associated with progressive granulocytopenia, increasing susceptibility to pyogenic infections, and a fatal termination in early childhood. Associated stigmata include partial albinism with photophobia, decreased production of tears, and excessive sweating. There is increasing

splenomegaly and moderate generalized lymphadenopathy. An unusual encephalomyelitis observed at postmortem examination was reported by Donohue and Bain.

## THE LEUKEMIAS

Leukemia is a fatal disease of unknown cause characterized by uncontrolled proliferation of leukocytes and their precursors.

The various forms of leukemia are classified according to the anticipated acute or chronic course of the disease and according to the predominant type of cell involved. Leukemia in childhood is usually an acute disease of relatively short duration (over 90 per cent), but chronic leukemia is being recognized with increasing frequency in children and may run a course of several years. The response of some children with leukemia to suppressive therapeutic agents makes separation into acute or chronic forms increasingly meaningless. The type of cell predominantly involved in leukemia offers a basis for classification. Myelocytic, lymphocytic, monocytic and other much less common leukemias (eosinophilic, megakaryocytic) are differentiated. In children, however, the predominating cell is often so undifferentiated morphologically ("stem cell") that a specific diagnosis according to origin of the cell cannot be made.

Leukemia occurs more often in the first five years of life than at any other age period, with a second peak at eight to nine years. Congenital leukemia is rare.

Leukemia is somewhat more common in males than in females, but not to the same degree in children as in adults. There are no detectable relationships to race, geographic factors or social or economic conditions. An unexpectedly high incidence of acute leukemia is found in association with mongolism, especially on a congenital basis.

**Pathology.** The pathologic changes in leukemia are related to the extensive primary proliferation of leukopoietic tissue and to secondary changes consequent upon disturbed function of involved organs.

Lymph nodes, spleen, liver and kidneys are usually enlarged, owing to the large amounts of proliferating leukemic tissue. There is ordinarily almost complete replacement of fatty marrow by grayish-red leukemic marrow. On section the normal splenic architecture is lost in an overgrowth of homogeneous red pulp. The liver is smooth and often made grayish-yellow by the excessive content

of leukopoietic tissue. The kidneys show leukemic infiltration extending along the medullary cords into the cortex. Extensive proliferation of leukemic foci, which is being found with some frequency in and about the central nervous system, may depend upon failure of antileukemic agents to cross the blood-brain barrier in effective concentration. Osseous changes can probably be explained by vigorous osteoblastic and osteoclastic activity and by destruction of bone by leukemic cells in areas which become free of endosteal covering.

Extensive hemorrhages may occur into parenchymal organs, into the retroperitoneal space, into subserosal areas of the bowel and pleura and into the central nervous system. Areas of ulceration and of extensive secondary infection may be encountered anywhere in the body.

**Clinical Manifestations.** The symptoms of leukemia are due (1) to hypermetabolism associated with rapid growth and destruction of leukemic tissue, (2) to bone marrow dysfunction, and (3) to disturbances of organs involved in leukemic proliferation.

The increase in metabolism is manifest by fever, weight loss, weakness and fatigue. Evidence of bone marrow dysfunction is reflected by the inability to produce adequate numbers of erythrocytes, platelets and normal leukocytes. Pallor and weakness accompany anemia; bleeding and easy bruising are associated with thrombocytopenia; and extensive infections, especially of the oral cavity and pharynx, are associated with the deficiency in normal granulocytes. These symptoms may develop with striking rapidity early in the course of leukemia in children. The overgrowth of leukemic tissue in various organs will give rise to local and systemic symptoms of varying severity. Lymphadenopathy and splenomegaly may be found early. Bone pain due to extensive osseous involvement is often a striking feature. Leukemia in other organs may lead to enlargement of liver, kidneys and testes and to symptoms of central nervous system involvement. Icterus, altered protein metabolism and azotemia may reflect functional disturbances, but usually not until late in the course.

Skin infections are common. Necrotic erythematous areas may be encountered late in the course of the disease in the submandibular and axillary areas as an extension from involved lymph nodes. Leukemic involvement of the skin is rarely seen in chil-

dren, but may occur as small yellow, well circumscribed, elevated nodules, which appear with amazing rapidity, especially in infants with myelocytic leukemia.

The hemorrhagic tendency universally present in acute leukemia is strikingly manifest by petechiae, purpura and extensive ecchymoses. Bullous, necrotic lesions may develop which rapidly become secondarily infected.

The mucous membranes are often involved; gums and oral mucous membranes, especially, may be involved early in bleeding and in necrotic ulcerations likely to be covered with a characteristic gray membrane. The gums may be greatly hypertrophied and at times painful.

Enlargement of lymph nodes in acute leukemia is usually not marked and may be absent. Deep-seated lymph nodes are usually more strikingly enlarged than the peripheral ones. Mediastinal involvement may be extensive and infrequently lead to respiratory distress or to pleural effusion. Enlargement of abdominal nodes may be extensive and may explain the rather common episodic abdominal pain.

Enlargement of the spleen is usually present in acute leukemia, but not so marked as in chronic leukemia. It usually has a soft edge and is often somewhat tender.

Though early symptoms referable to the gastrointestinal tract are unusual, anorexia, nausea and abdominal pain are often present. A hemorrhagic diarrhea may be troublesome, and extremely painful necrotic ulcerative lesions of the lower rectum and perirectal areas may occur when agranulocytosis is marked.

Hematuria may be the presenting complaint, and painful episodes of ureteral colic may occur. The kidneys are usually enlarged, and there may be alterations in the pyelogram. Overgrowth of leukemic tissue and extensive hemorrhage may lead to renal failure.

Patients with acute leukemia are frequently first seen because of bone pain or arthralgia. Roentgenograms usually demonstrate changes in the bones of symptomatic areas.

Retinal hemorrhages are common. Exophthalmos may result from retrobulbar hemorrhage or leukemic overgrowth, and bleeding into the lids, vitreous or scleras is not unusual. Deafness may develop after hemorrhage into the labyrinth or auditory nerve. Intracranial hemorrhage is the most common immediate cause of death in children with acute leukemia. Proliferative or hemorrhagic in-

volvement of the central nervous system may lead to a variety of symptoms in acute or chronic leukemia, depending on the areas of the brain or spinal cord involved.

*Chronic leukemia* is uncommon in children, is almost always myelocytic in origin and usually has its onset after the age of eight years. Males seem to be more frequently affected than females. Chronic lymphocytic and monocytic leukemias are rarely, if ever, seen in children.

The onset of symptoms in chronic myelocytic leukemia is insidious, and first knowledge of it often comes from examination of the blood for an unrelated circumstance or because of an asymptomatic splenomegaly. Splenomegaly, slight anemia, and weakness are the only consistent manifestations; bone pain is an occasional complaint. In early infancy such manifestations of disturbed hematopoiesis as thrombocytopenia and hemorrhage may be more prominent.

Splenic enlargement is progressive and may attain enormous proportions, giving rise to anorexia, vomiting and left upper quadrant discomfort. Progressive anemia of moderate degree with pallor and weakness may develop over a period of months. Susceptibility to infections and to hemorrhagic manifestations does not usually occur until late. Terminally, the child has fever, infection, rapidly progressive splenomegaly and hemorrhagic symptoms with a predominance of immature forms in the blood and extreme leukocytosis.

**Laboratory Data.** A diagnosis of leukemia should never be made if the laboratory evidence is equivocal. Abnormalities are usually found in peripheral blood, bone marrow, certain chemical constituents of the blood and in roentgenograms of the long bones.

A moderate to severe normochromic anemia with absent reticulocyte response is usual. There is nearly always a marked thrombocytopenia in acute leukemia, but in chronic myelocytic leukemia there may be a marked increase in platelets with counts up to 1 million per cubic millimeter or more.

Leukopenia is found at the initial examination in over 65 per cent of children with acute leukemia; occasionally there are moderate to marked degrees of leukocytosis. In chronic leukemia counts over 200,000 per cubic millimeter are common. Much more important than the numbers of leukocytes are the morphologic characteristics of the leukemic cells. Careful examination of properly prepared blood films will almost always reveal immature and morphologically abnor-

mal leukocytes. The origin of the abnormal leukocytes should be identified if possible, since certain therapeutic agents are more effective against one cell type than another. In acute leukemia, however, this is most often impossible. The majority of mature cells in peripheral blood are lymphocytes, but this does not mean that the immature forms are necessarily of lymphatic origin, but rather that the leukemic overgrowth in marrow has reduced the production of normal granulocytes.

In chronic myelocytic leukemia identification of the cell type is usually not difficult, the great increase in leukocytes consisting of mature granulocytes, metamyelocytes, myelocytes and, at times, a few myeloblasts. Eosinophilic and basophilic granulocytes are also ordinarily increased.

*The diagnosis of leukemia should not be made without examination of aspirated or surgically removed bone marrow.* Except in most unusual circumstances the marrow will show overgrowth of abnormal leukopoietic tissue; few normal hematopoietic elements are found. Megakaryocytes and erythropoietic precursors are greatly decreased. At times the bone marrow in acute leukemia may present the picture of aplastic anemia without evidence of abnormal leukopoietic tissue. In such instances the diagnosis of leukemia *should be deferred* until confirmation is possible, and exhaustive search should be made for other causes of aplasia of marrow, which might be amenable to therapy.

In chronic myelocytic leukemia the disturbance in bone marrow is less striking, but the experienced morphologist can readily recognize alterations in myeloid cells and an interference in erythropoiesis. Megakaryocytes may be greatly decreased or present in abnormally high numbers. Differentiation from granulocytic leukemoid reactions may be difficult.

Excessive production and destruction of leukocytes lead to an elevation of the uric acid level in the blood, which may be augmented by leukocytotoxic agents. Urinary excretion of uric acid may be so much increased by a rapid reduction of a high leukocyte count that precipitation of urate crystals may obstruct the urinary tract.

The blood levels of glutathione, phosphorus and alkaline phosphatase are also commonly increased. Increases in the pressure, protein content and leukocyte count of the cerebrospinal fluid may also occur.

A wide variety of roentgenographic abnor-

malities may be demonstrated in acute and in chronic leukemia. These include enlargement of mediastinal lymph nodes, pneumonitis, pleural effusion and enlargement of the liver, spleen or kidneys. Certain alterations in bones are highly suggestive of leukemia and are found in over two thirds of children with the disease. There are four general types of lesions: osteolytic lesions, irregular areas of osteosclerosis, areas of diminished density traversing the metaphysial ends of long bones, and subperiosteal new bone formation. Such lesions may be responsible for spontaneous fractures and for collapse of vertebral bodies. The skeletal lesions may disappear in response to antileukemic or to local roentgen ray therapy.

**Differential Diagnosis.** The bone pain and arthralgia of early leukemia often suggest osteomyelitis, rheumatic fever, Still's disease or brucellosis. Leukemia may be suggested by the lymphadenopathy of tuberculosis, pyogenic lymphadenitis, Hodgkin's disease, lymphosarcoma or cat-scratch fever. The generalized lymphadenopathy and cellular changes in the blood of infectious mononucleosis may require bone marrow biopsy for differentiation.

Hemorrhagic phenomena in the form of petechiae and purpura may be the presenting symptoms in acute or advanced chronic leukemia and may suggest scurvy, aplastic anemia, idiopathic thrombocytopenic purpura or purpura of other causes. The differentiation of leukemia from aplastic anemia may be particularly difficult and should not be attempted without a generous specimen of surgically removed marrow.

The increased number of lymphocytes in the blood in pertussis, infectious mononucleosis or infectious lymphocytosis may suggest leukemia and must be differentiated by clinical and laboratory means.

**Course and Prognosis.** Without antileukemic therapy the course of acute leukemia is generally one of progressive deterioration. Infections of the mouth and pharynx leading to pneumonia or septicemia may result in early death. Intracranial hemorrhage is the most common terminal event. In somewhat less than 10 per cent of patients a period of complete normality may occur without "specific" therapy, during which time it is impossible to find clinical or laboratory evidence of the disease. Such "spontaneous remissions" usually follow infections, or the transfusion of large quantities of blood, and usually last only a few weeks. The duration of acute leu-

kemia may be only a week or so, but is more likely to be six to nine months. With suppressive antileukemic therapy, life can be prolonged in the majority of instances for months to a year or so. Chronic myelocytic leukemia is compatible with relatively normal activity for two or more years.

**Treatment.** When the diagnosis has been made beyond any possible doubt, the nature and prognosis must be frankly discussed with the parents. Efforts should then be directed to attaining as many happy and comfortable days as possible for the child.

Supportive measures such as blood transfusions, chemotherapy and sedative and analgesic drugs should be used judiciously. Antibiotic drugs should be used when indicated, but prolonged administration should be avoided, since it may lead to infections with resistant organisms. Prophylactic use is unwarranted. The tetracyclines should not be used in conjunction with the folic acid antagonists, since they may counteract their effect.

A number of agents may have a depressant or lytic effect of variable duration upon the proliferation of leukemic tissue. Such agents include the folic acid antagonists, cortisone, and a purine analog, 6-mercaptopurine. In chronic leukemia temporary modification of the leukemic process may also be obtained through the use of urethane, roentgen ray therapy or certain compounds related to nitrogen mustards.

The introduction by Farber of antagonists of folic acid to the group of antileukemic agents has been the most significant therapeutic measure to date. These agents are thought to exert their beneficial effects by interference with the use of folic acid by intracellular enzyme systems. Leukemic cells require much more folic acid than normal cells, and their division is impaired with antimetabolite therapy, while metabolism of normal cells is not significantly altered. With the administration of these antimetabolites from 25 to 50 per cent of children with acute leukemia experience complete remissions, and an additional 20 or 30 per cent have significant clinical improvement with partial remissions. Of the many analogs of folic acid, aminopterin and Methotrexate are most effective; owing to its lesser toxicity, the latter is most often used. Methotrexate is given orally in doses of 2.5 to 5 mg. a day. The therapeutic effect may be noted within a few days, but usually a remission will occur only after two to five weeks of therapy. When remission has occurred, therapy may be con-

tinued with smaller doses. Eventually the response to therapy becomes less satisfactory, and other therapeutic agents should be substituted.

In toxic doses the antagonists of folic acid exert devastating effects upon normal cells. Those of the gastrointestinal mucous membranes appear to be most susceptible. Nausea, vomiting, diarrhea and ulceration of the buccal mucous membranes are the common early signs of toxicity and necessitate prompt discontinuation of therapy. Hematopoietic activity may also be suppressed by these agents. Peripheral blood cell counts should therefore be performed frequently, and therapy discontinued before dangerous leukopenia or thrombocytopenia develops.

Cortisone in divided doses totaling 100 to 200 mg. daily is also helpful in the management of acute but not chronic leukemia; nearly all patients receive some clinical benefit, and about 60 per cent show hematologic improvement as well. Improvement is often of only a few weeks' duration.

The purine analog, 6-mercaptopurine, induces temporary remission in acute leukemia and in some cases of chronic myelocytic leukemia. The drug is given in doses of 2 mg. per kilogram of body weight per day until a fall in leukocyte count is observed. Since leukocytes may be very sensitive to this drug and since the maximal effect of a given dose is often delayed a few days, the leukocyte count should be closely followed during therapy and the drug discontinued at the first sign of a decrease in the number. The chief manifestation of toxicity is interference with hematopoiesis, which may be severe and irreversible. If no response is obtained within three to four weeks, the dose may be doubled, but this is rarely necessary.

Among other cytotoxic agents which have been used for chronic leukemia are a nitrogen mustard, such as CB1348, triethylene melamine (TEM), thio-triethylenephosphoramide (thio-TEPA) and urethane. These substances are contraindicated in acute leukemia in children.

Roentgen ray therapy may be helpful in temporary control of the recurrent bone pain. Twenty-five to 50 roentgens over the site of pain on three or four successive days will usually produce relief. Roentgen ray therapy may also be useful in chronic myelocytic leukemia.

In acute leukemia the choice of therapeutic agents will depend upon the clinical status, hematologic findings and previous therapy.

The following generalizations may be helpful, but individualization of therapy is essential. If the child when first seen is acutely ill with a leukocyte count of more than 50,000 per cubic millimeter, cortisone is given, since an early beneficial clinical effect may be expected. If the leukocyte count is low and the patient is not in poor clinical condition, therapy with folic acid antagonists is preferable. Benefit is apt to be of longer duration than that obtained from cortisone, but may be delayed two to three weeks in appearance.

When, after prolonged or recurrent courses of therapy, the patient fails to respond to folic acid antagonists, 6-mercaptopurine may be given if the patient is not in a poor clinical state. If the leukemic process is active and the patient's condition poor, cortisone is given initially. When there is no longer a response to administration of 6-mercaptopurine, folic acid antagonists may be given again in the hope that resistance to the drug may have

lapsed. Ultimately leukemia becomes unresponsive to any currently available agent.

The child with leukemia is happiest and most comfortable in his usual environment. Therapy should aim at minimal hospitalization, with as few diagnostic and therapeutic procedures as are compatible with good care. The attitudes of parents and friends toward the seriously ill child should permit him to live as normal a life as possible. Pampering, segregation, puzzling attitudes toward the child and unusual arrangements by which it is hoped to cheer him may provoke more anxiety and bewilderment in him than pleasure. The child's activities should be governed by his own desire and abilities. There are no unusual dietary needs.

So long as satisfactory relationships can be maintained, home care is preferable, but parents are at times unable to cope with the situation, and hospitalization offers desirable respite.

## DISEASES OF THE BLOOD ASSOCIATED WITH DEFECTS IN HEMOSTASIS

When very small vessels, such as arterioles, venules and capillaries, are injured, reflex contraction of smooth muscle in the small arterioles and the precapillary sphincter occurs which leads to reduced flow. There is a local accumulation of platelets at the site of injury to endothelial surfaces forming a hemostatic plug, which seals the defect in the vessel. Disintegrating platelets release a factor (serotonin) producing prolonged local vasoconstriction. The retention of blood within injured small vessels thus appears to depend upon the integrity of the vessel endothelium and normal function of adequate numbers of platelets. There is no evidence that the formation of a fibrin clot is important here. For example, the patient with hemophilia, who cannot form a clot, does not bleed abnormally from trauma confined to small vessels.

*Defects in hemostasis in small vessels* may reside in the vessel or in the platelets. Regardless of the cause, the amount of blood lost will not be large, even if the petechial or purpuric lesions are widespread. Large extravasations in the forms of hematomas, hemarthroses or hemorrhages are not expected in vascular or platelet disorders unless a large number of vessels are traumatized at one time. Epistaxis, however, is an exception, and

bleeding from a small local lesion may lead to prolonged and severe blood loss.

The integrity of vascular endothelium depends upon many factors. Ascorbic acid is essential for production of the intercellular cement substance of endothelial cells. Rutin (vitamin P, eriodictyol, hesperidin) is apparently also involved in capillary permeability, but its mode of action is unknown, and it has no proved therapeutic role. Anoxia may lead to local or general increases in permeability of capillary endothelium, and allergic factors may produce localized or general injury. In many instances the hydrostatic pressure in the vessels will determine the likelihood of extravasation at a site of injury.

*Bleeding from injuries to large vessels* is controlled in part by the same mechanisms which control bleeding from small vessels. There is local spasm of both small and large vessels and accumulation of platelets at the site of injury. There is, in addition, eventual formation of a fibrin clot which bridges and seals the area of injury.

The *formation of the clot* is a complicated process depending upon local upset of a dynamic equilibrium between formation and dissolution of clotting factors. The final step in the process is the conversion of the solu-

protein fibrinogen to an insoluble form, fibrin, which forms a mesh of protein strands trapping red cells, white cells and platelets. Contraction or retraction of the clot occurs, which tends to close the defect in the injured vessel. An adequate supply of functional platelets is essential to retraction of the clot.

Fibrinogen is formed in the liver. It is present in the blood normally in concentrations ranging from 250 to 400 mg. per 100 ml., an amount which represents the average need for about three days. The transformation of fibrinogen into fibrin occurs when thrombin is formed from a protein precursor, prothrombin. Prothrombin is formed mainly in the liver and, like fibrinogen, exists in the blood stream in an amount equal to the needs for about three days. Vitamin K is necessary for the synthesis of prothrombin.

The conversion of prothrombin into thrombin depends upon an increase in thromboplastin activity. Several substances present in small amounts in blood plasma contribute to the elaboration of active thromboplastin, in addition to a factor present in platelets and in tissue juices. These substances in plasma include AHG (thromboplastinogen, antihemophilic globulin), PTC (plasma thromboplastin component) and PTA (plasma thromboplastin antecedent), each of which may have an inactive and an active form.

In addition to thromboplastin activity three other factors regulate the conversion of prothrombin into thrombin. The first is ionized calcium, in the absence of which the conversion cannot take place. The other two are catalytic enzymes which affect mainly the rate of prothrombin conversion. One is known as *labile factor*, since its activity is lost in stored blood in a period of two weeks. The other retains activity under these circumstances and is known as *stable factor*. Both accelerators have many synonyms. Vitamin K is necessary for production of stable factor, which with labile factor is produced in the liver. Each probably exists in inactive and in active forms, and their activation is probably accomplished by small amounts of thrombin.

Many of these clotting factors have associated antifactors, which actively neutralize them as they are formed and tend thereby to preserve the fluidity of blood. In man a heparin-like substance displays predominantly antithrombin activity and is apparently formed for the most part in the mast cells of the reticuloendothelial system. A fibrinolytic enzyme is normally present in blood in an inactive form (profibrinolysin or plasmino-

gen) and in an active form (fibrinolysin or plasmin). Abnormal anticoagulants may be formed in a variety of conditions (shock, transfusion reactions, disorders of pregnancy, prostatic cancer). Antithromboplastic substances have been observed in hemophilia and in lupus erythematosus.

The clot-promoting substances may be only sluggishly responsive initially to the call for clot formation. The process is rapidly accelerated through a feedback mechanism which gives thrombin the property, not only of first initiating fibrin formation, but also of labilizing platelet activity, of accelerating thromboplastin formation and of activating the labile and stable factors which increase the rate of prothrombin conversion.

The formation of fibrin ceases when the free thrombin which activated the clotting process is inactivated. Further clot formation will then depend upon the further addition of active thromboplastin to the blood.

**Platelets.** Blood platelets are small, refractile, oval or irregularly shaped bodies, 2 to 5 microns in greatest diameter, with finely granular basophilic cytoplasm, but without well defined nuclear structure. They are produced in bone marrow from megakaryocytes. Accurate counts of platelets are difficult to obtain, owing to the ease with which these elements undergo lysis and agglutination. Normal counts vary from 150,000 to 400,000 per cubic millimeter. The life span of the platelet in the blood stream in man is four to eleven days. In the dog, after removal of all circulating platelets, the platelet count returns to normal in three to four days.

In the elucidation of the functions of platelets at least four active "factors" and certain other properties have been identified. Platelet factor I accelerates the conversion of prothrombin to thrombin; factor II accelerates the conversion of fibrinogen to fibrin; factor III has thromboplastic activity and with other thromboplastin factors (AHG, PTC, PTA, and the like) converts prothrombin to thrombin; and factor IV neutralizes heparin. Serotonin can be found in lysed platelets in a concentration of 0.5 to 1.3 micrograms per  $10^9$  platelets. This important substance produces vasoconstriction by action on the smooth muscle of small vessels and initiates the release of epinephrine from the adrenal medulla.

Much of the activity of platelets is associated with their agglutination. Agglutination is enhanced in vivo by contact with roughened endothelial surfaces or foreign particles,

by vascular stasis and by thrombocytosis. Owing to the readiness with which platelets agglutinate on contact with a foreign surface, a universally satisfactory system for examining their agglutination in vitro is not available. Current evidence indicates that the immunologic and antigenic properties of platelets reside in two major platelet antigens which give rise to four major platelet groups, analogous to the major red blood cell groups. Iso-immunization to platelets may occur after heterospecific blood (platelet) transfusion or pregnancy. Auto-immunization is the suggested mechanism for many instances of idiopathic thrombocytopenic purpura.

Thrombocytosis may accompany splenectomy, trauma, hemorrhage, lead poisoning, rheumatic states, bacterial infections, polycythemia vera, myeloid leukemia and hyperadrenalism.

#### LABORATORY TESTS USEFUL IN THE STUDY OF PATIENTS WITH A BLEEDING TENDENCY

The evaluation of patients with an abnormal bleeding tendency includes tests of vascular integrity, of platelet function and of adequacy of the clotting mechanism. The bleeding time and the tourniquet test are helpful in evaluating the integrity of the mechanisms responsible for hemostasis in small vessels. Each will be abnormal if there is a generalized defect in vascular integrity or platelet function, as in scurvy, cutis hyperelastica or thrombocytopenia. The *tourniquet test* is the more generally useful. It should be performed with a blood pressure cuff inflated to a pressure midway between systolic and diastolic pressures and maintained there for eight minutes. The *bleeding time* is widely used, but is subject to great error. A careful examination of the formed elements in the peripheral blood, with estimation of the number of *platelets*, is essential. If there is a decreased number of platelets, an examination of *bone marrow* should be made to establish whether an adequate number of megakaryocytes is present, and to account, if possible, for their absence. Observation of *clot retraction* provides evidence of the adequacy of platelet function.

A wide variety of tests can be used to measure the functional adequacy of the clotting mechanism. In hypofibrinogenemia clotting time is normal, but the clot is small and friable. In the absence of fibrinogen (afibrin-

ogenemia) the blood is incoagulable. The clotting time is prolonged in deficiencies of plasma thromboplastin factors. Deficiencies in platelet thromboplastin factors may also occur, but rarely give rise to prolonged clotting time; if the formation of active thromboplastin is impaired, the *prothrombin consumption test* will usually be abnormal.

Certain tests are helpful in distinguishing deficiencies of the various plasma thromboplastin factors. Antihemophilic globulin loses its activity in stored plasma, so that a clotting defect corrected by stored plasma must be the result of PTA or PTC deficiency. Plasma thromboplastin component is adsorbed on barium sulfate, so that normal plasma so treated will not correct the defect in PTC deficiency, whereas it will readily correct the defect in clotting due to AHG, if fresh, and will correct PTA deficiency even if stored. Serum retains PTC and PTA activity, but loses AHG activity. Differentiation of AHG, PTC and PTA deficiencies will be most certain when samples of blood from known cases of each of the three deficiencies are available. It will then be possible to demonstrate that the addition of a tenth part of the plasma of any one to either of the other two will correct the clotting defect, whereas the homologous defect will not be corrected. By similar mixing techniques deficiencies of other newly found factors (such as Hageman, Stuart or Car) may be identified.

The most sensitive test for adequacy of thromboplastin factors is the *thromboplastin generation test*. When plasma adsorbed by barium sulfate, serum and platelets are brought together, all factors needed for thromboplastin formation should be present. When, after incubation, aliquots of such a mixture are added with calcium ion to normal plasma, the time needed for clotting is a measure of the developing thromboplastin activity. Substitution of the adsorbed plasma, serum or platelets of a patient with a hemorrhagic disorder into a system of normal reagents makes possible specific identification of deficiencies of AHG, PTC, PTA or platelet factors.

Defects in the formation of thrombin do not result in increases in the clotting time, except in unusually severe instances. The *one-stage prothrombin test*, however, which measures the clotting time of citrated blood when thromboplastin and calcium are added in adequate amounts, will ordinarily reflect disturbances in thrombin formation. A prolonged prothrombin time reflects an inade-

quate level of prothrombin or a deficiency of prothrombin accelerators. The deficiencies can be differentiated in a variety of ways. For example, if one part of stored plasma is added to nine parts of the plasma of a patient with labile factor deficiency, no correction of the prolonged prothrombin time of the patient will occur, whereas fresh normal plasma will correct the clotting defect. Further, plasma adsorbed on barium sulfate loses both prothrombin and stable factor. Such plasma will not correct the defect in thrombin formation in a patient deficient in either of these substances. Normal serum is ordinarily free of prothrombin and labile factor, but retains stable factor activity. Serum, then, will accelerate prothrombin conversion in a system containing adequate amounts of prothrombin, labile factor, calcium and thromboplastin. Failure of acceleration would indicate an absence of stable factor.

The *two-stage prothrombin test*, which measures the amount of thrombin produced, may give additional useful information, but is cumbersome for routine use.

Increases in anticoagulant factors are not common in children. Increase in antithromboplastin activity may be encountered most commonly in the patient with hemophilia, as a complication of replacement therapy with AHG in any form. Increases in normal antithrombin factor rarely, if ever, occur, but heparinoid substances are increased in states of shock, during intensive radiation therapy or during administration of nitrogen mustard.

One or more fibrinolytic substances may be present in blood under normal or pathologic conditions. They are detected principally by their interference with the stability of the clot. They may on occasion cause such rapid lysis of the clot that its formation may not be detected, and the blood may appear to be incoagulable. The anticoagulant formed under circumstances of surgical or anaphylactic shock or in severe liver disease may be a fibrinolysin. Bleeding disturbances due to abnormal anticoagulants have rarely been demonstrated in children, but it is anticipated that they may be met with greater frequency as knowledge of them increases.

Heparin therapy is occasionally used for anticoagulant purposes in children, particularly after splenectomy, when hypercoagulability due to thrombocytosis may be present. The dose is determined principally by the clotting time, which must be measured in *venous blood* with great care. Protamine sulfate, given intravenously, rapidly counteracts the effects of an overdose of heparin.

Unlike that of heparin, the action of Dicumarol and related anticoagulant substances is on the production of prothrombin in the liver. The therapeutic use of Dicumarol must be regulated by the prothrombin time rather than by the clotting time. The effect of Dicumarol is delayed until preformed prothrombin can be depleted. The action of Dicumarol is reversed by adequate doses of vitamin K within a few hours or by the transfusion of blood.

## DEFECTS OF HEMOSTASIS IN SMALL VESSELS

Petechiae and purpura, characteristic of bleeding from small vessels, may be cardinal features of a wide variety of diseases. The major conditions may be classified according to their vascular or platelet origin as follows:

- I. Vascular defects
  - A. Congenital
    1. Cutis hyperelastica (Ehlers-Danlos)
    2. Pseudoheremophilia
    3. Hereditary hemorrhagic telangiectasia
    4. Pulmonary hemosiderosis
    5. Idiopathic hematemesis and melena
  - B. Acquired
    1. Scurvy
    2. Anaphylactoid purpura (Henoch-Schoenlein)
    3. Toxic angitis due to bacterial or toxic agents
- II. Defects in platelet function
  - A. With normal platelet count
    1. Hereditary thrombocythemia
    2. Thrombocytopathic purpura

### B. With thrombocytopenia

1. With normal numbers of platelet precursors in marrow (megakaryocytes)
  - a. Idiopathic thrombocytopenia
  - b. Thrombocytopenia due to iso-immunization in the newborn
  - c. Thrombocytopenia due to secondary hypersplenism
  - d. Thrombotic thrombocytopenia
2. With deficient platelet precursors in marrow
  - a. Aplastic anemia
  - b. Leukemias

## ANAPHYLACTOID PURPURA (See p. 920)

## OTHER VASCULAR DEFECTS ASSOCIATED WITH BLEEDING TENDENCY

Congenital defects in the structure of small blood vessels may give rise to purpura or to bleeding tendency in children.

In *hereditary familial telangiectasia* small dilatations of capillaries may occur at the finger tips, on the face and in the mucous membranes of the mouth and the nose, which may bleed profusely. This disease is rarely encountered before the age of eleven or twelve years.

In *cutis hyperelastica* (Ehlers-Danlos syndrome, p. 1277) an inherited anomaly of connective tissue is manifest by overproduction of elastic tissue. The skin is hyperelastic, joints are hyperextensible, and there is poor connective tissue support for small cutaneous vessels, which bleed profusely upon slight trauma. Wounds heal with delicate "tissue paper" scars. Serious hemorrhage may follow skin biopsy in these patients.

*Toxic vascular purpura* may be a manifestation of many infections and poisons in children. Acute meningococcemia may be associated with extensive purpura (Waterhouse-Friderichsen syndrome), as may septicemia due to other organisms. Rarely the platelet count will be reduced in such instances. In some infections, such as subacute bacterial endocarditis, petechiae or purpura may be embolic in origin, but more often the vascular injury associated with infection appears to be due to a toxin.

Iodides, arsenicals, salicylates, atropine, belladonna and other drugs have been reported to be responsible for purpura without thrombocytopenia. Such reactions to drugs appear to depend upon idiosyncrasy. Snake venoms, on the other hand, may have a specific toxic action for endothelium which results in purpura. In scurvy the intercellular endothelial cement substance is not produced in adequate amounts, and purpura may be a prominent aspect of this disease.

### IDIOPATHIC THROMBOCYTOPENIC PURPURA

Idiopathic thrombocytopenic purpura (ITP) is characterized by spontaneous small hemorrhages into skin, mucous membranes and many other tissues, and is associated with a striking deficit in the number of circulating platelets and with normal or increased numbers of megakaryocytes in the bone marrow. Sixty-five to 85 per cent of all cases occur in children under twelve years of age, the highest incidence appearing to be between the ages of three and seven years. The predominance of female patients in adults does not occur in children. The disease is uncommon in Negro children.

**Etiology and Pathogenesis.** The role of preceding "sensitizing" infections, which occur in about 60 per cent of instances, is not clear. It has been suggested that the autoimmune type of acquired hemolytic anemia and idiopathic thrombocytopenia are due to similar immunologic abnormalities, and "platelet agglutinins" have been demonstrated in patients with thrombocytopenia, analogous to the auto-agglutinins for erythrocytes. It appears that the spleen may (1) produce substances adversely affecting capillary permeability, (2) be the site of production of anti-platelet antibodies, and (3) be the most active site of removal of "sensitized" platelets from the circulation.

It seems clear that the platelet deficiency is due to factors outside the platelet, since the life span of normal platelets infused into patients with thrombocytopenic purpura is markedly shortened. By contrast, the life span of transfused platelets is generally normal in patients with thrombocytopenia due to hypoadactivity of the bone marrow.

**Clinical Manifestations.** Idiopathic thrombocytopenic purpura occurs in two distinct forms: an acute self-limited form most common in children and a chronic, recurrent form relatively infrequent in children.

In the acute form the onset is sudden and often occurs one to four weeks after a mild respiratory infection or occasionally after one of the exanthems, especially measles.

The first signs are usually spontaneous petechiae and purpura involving the skin and buccal and conjunctival mucous membranes. Bleeding may be especially prominent over bony prominences or at the sites of mild trauma, where large ecchymoses may appear. The lower extremities, the buttocks and the extensor surfaces of the arms are almost always involved, and in the more severe instances hemorrhages are widely scattered over most of the body surface. At the onset the child rarely has other significant symptoms and usually does not appear acutely ill.

Hemorrhages from the urinary tract, vaginal and nasal mucous membranes or the gastrointestinal tract occur in severely ill patients. Hemorrhage into joints or into the pleural or peritoneal spaces is unusual. Intracranial hemorrhage is an uncommon complication, but is the most common cause of death. The neurologic manifestations vary widely; for example, from transient localized paresis to decerebrate rigidity. The spleen is not regularly palpable and is never greatly

enlarged. Generalized lymphadenopathy is not characteristic.

Approximately 10 to 15 per cent of the cases in children are of the chronic variety. The onset is less dramatic than in the acute form. The presence of a hemorrhagic disorder is often recognized only when there is profuse bleeding with such trauma as that of dental extraction or other surgical procedures or with epistaxis or menarche. The history in such instances, however, often discloses a tendency to easy bruising and excessive hemorrhage from minor wounds for months or years. Periods of excessive bruising and bleeding may alternate with periods of prolonged good health. In about one fourth of instances there is a family history of bleeding tendency.

Physical findings are usually less extensive in the chronic form than in the acute one. Small ecchymoses may be found at sites of minimal trauma, and a few petechiae are commonly seen in the oral cavity.

**Laboratory Data.** The platelet count is always below 100 thousand per cubic millimeter and may be less than ten thousand. A normochromic anemia with a compensatory reticulocytosis may be present if bleeding has been severe. In the chronic form, if epistaxis or menorrhagia has recurred frequently, iron deficiency may result from loss of blood. A moderate leukocytosis with an increase in the granulocytic forms is to be expected when intracutaneous bleeding is extensive, and there may be a slight increase in eosinophilic leukocytes.

The tourniquet test is usually strongly positive, and the bleeding time is generally prolonged. The clotting time is normal, but clot retraction is delayed and incomplete, and the prothrombin consumption test shows defective utilization of prothrombin.

The changes in the bone marrow are difficult to evaluate. Megakaryocytes are thought by some to be increased in number, to be immature and to have less than normal "budding" activity. There may be an increase in eosinophils, a feature thought by some to indicate an ensuing remission.

Some affected children have substances in their plasma which produce thrombocytopenia. They may be demonstrated *in vivo* by injecting serum from the thrombocytopenic patient into normal persons, or *in vitro* as agglutinins of platelets by the techniques of Harrington.

**Diagnosis.** In all patients with thrombocytopenia the bone marrow should be studied, since aplastic anemia and leukemia are prom-

inent diagnostic possibilities. If megakaryocytes are present in normal numbers and granulopoiesis and erythropoiesis are not altered, and if the patient is free of symptoms other than those associated with the low platelet level, the diagnosis of idiopathic thrombocytopenia is strongly suggested.

Since splenomegaly is never marked in idiopathic thrombocytopenia, a moderate to marked enlargement in association with thrombocytopenia suggests the possibility of some other disturbance, especially leukemia, a primary reticuloendotheliosis or hypersplenism due to congestive splenomegaly.

In Banti's syndrome, thalassemia, Gaucher's disease and certain parasitic infections secondary hypersplenism may lead to reduction in the number of platelets and occasionally to hemorrhagic manifestations.

In the older child the possibility of lupus erythematosus must be considered; the demonstration of L.E. cells supports this diagnosis. Thrombotic thrombocytopenic purpura has reduced platelet counts and bleeding with a normal marrow; a hemolytic anemia and cerebral symptoms and the acuteness and severity of the illness are additional distinguishing factors.

**Course and Prognosis.** Seventy-five per cent of children recover within two months with supportive therapy, and another 10 to 15 per cent within four to six months. Occasionally spontaneous recovery is delayed for as long as a year. During the active phase the severity of symptoms may vary greatly. Recurrence of the acute form of the disease is rare.

About 10 per cent of children with this disease have the chronic form. Even during improvement in the clinical state the platelet count will remain low. About two thirds of these patients recover after splenectomy. Since the chronic form is encountered more commonly in girls, the possibility of excessive menstrual bleeding is an important consideration. Limited experience indicates that the initial menses may be accompanied by profuse and irregular blood loss, but that after the first few months relatively normal flow can be expected. Approximately 50 per cent of infants of mothers with chronic idiopathic thrombocytopenia have transient thrombocytopenia in the neonatal period.

**Treatment.** Initially a conservative program consisting in careful observation and supportive measures is usually justified. Transfusions of whole blood may be given to correct excessive blood loss. Infections

and carrier states involving pathogenic organisms should be treated with appropriate antibiotic agents. The patient with moderate or severe bleeding should be confined to bed in as atraumatic an environment as possible.

Unusual instances of severe bleeding may call for infusion of platelet-rich plasma or whole blood. In order to preserve blood platelets in useful form, it is necessary to transfer blood as directly as possible from donor to patient with tubing of nonwetable plastic material and glassware treated with silicone agents and preferably with ethylenediamine tetra-acetic acid (EDTA) as the anticoagulant. The survival of platelets even when transferred under optimal circumstances is only a few hours, but during this time bleeding may be controlled. The efficacy of platelet transfusions can be increased by using blood of persons with polycythemia vera. Platelet transfusions become less efficient with repetition.

The use of either ACTH or cortisone is best limited to the temporary control of severe bleeding. The effect of these agents on the platelet count is unpredictable.

Generally, splenectomy is considered only after the disease has been present for six to twelve months. It may be considered earlier when hemorrhagic manifestations are unusually severe and not controlled by ACTH or cortisone, or when adequate protection against trauma cannot be secured. Splenectomy may also be considered when a patient is approaching the menarche, or when an intracranial hemorrhage has occurred, with the hope of avoiding a repetition. Complete and lasting remissions can be expected in 60 to 70 per cent of children with chronic idiopathic thrombocytopenia. The remaining 30 to 40 per cent will have a persistence of the disease, but possibly with some lessening of the manifestations.

### THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura is a rare and, so far, invariably fatal disease, the salient features of which are extensive purpura with thrombocytopenia, hemolytic anemia and bizarre mental and neurologic manifestations. The cause is unknown, but available evidence suggests a state of hypersensitivity. There are no sex or racial predilections.

The primary process appears to be in small blood vessels with inflammatory and degen-

erative changes in their walls, and multiple small aneurysms in arterioles. The capillaries contain masses of amorphous material, thought to be agglutinated platelets, and proliferated endothelial cells. The widespread occlusion of small vessels leads to small infarcts and to foci of necrosis in the heart, brain and other organs.

**Clinical Manifestations.** The onset is usually sudden with extensive purpuric eruption, high fever, pallor and various neurologic findings. Occasionally the onset is insidious with weakness, vertigo and mild anemia. Usually the disease is of only a few days' duration, with rapidly falling hemoglobin level, icterus, coma and convulsions, leading to death. Splenomegaly and hepatomegaly may become marked.

**Laboratory Data.** There are anemia, reticulocytosis and erythroblastemia of varying degrees. The leukocyte count may be slightly or greatly elevated. The platelet count is always reduced. L.E. cells may frequently be encountered in appropriate preparations of the blood.

In the bone marrow there is a reactive myeloid and erythroid hyperplasia, and erythrophagocytosis and leukophagocytosis may be prominent. The characteristic vascular lesions have been observed in sections of marrow and can usually be demonstrated in biopsy specimens of the cutaneous lesions.

**Treatment.** Currently available therapy has failed to alter the course of this disease. Cortisone and ACTH have had no apparent effect.

### THROMBOCYTOPENIA IN THE NEWBORN

In the newborn infant thrombocytopenia most commonly accompanies a severe prenatal or postnatal infection, such as septicemia, syphilis, toxoplasmosis, torulosis or cytomegalic inclusion disease, which may greatly depress marrow activity. Congenital aplastic anemia (Fanconi), congenital leukemia and congenital absence of megakaryocytes are rare causes of thrombocytopenia in the newborn. In these conditions megakaryocytes will be few or absent in marrow.

In many infants of mothers with thrombocytopenic purpura there is a transient thrombocytopenia of four to six weeks' duration, due to transplacental passage of antiplatelet substances. A similar transient thrombocytopenia may occur when an infant is born to a mother who has been iso-immunized by a heterospecific platelet transfusion or

through pregnancy. The thrombocytopenia occasionally seen in association with hemolytic disease of the newborn may have such an origin. In these immunologic disorders the numbers of megakaryocytes in marrow are normal, and no specific measures are ordinarily necessary. In exceptional instances a platelet transfusion may be helpful.

### THROMBOCYTOPENIA AND GIANT HEMANGIOMA

A severe hemorrhagic disorder, with thrombocytopenia, has been encountered in infants

with large hemangiomas, due apparently to sequestration of platelets within the extensive vascular bed of the tumor. Platelet production in bone marrow appears to be normal.

Extensive hemorrhage into the hemangioma may cause rapid enlargement of the tumor and accentuation of the thrombocytopenia. Radiation therapy may be used in the hope of initiating regression of the tumor, but may be difficult, owing to its great size. Steroid therapy is of doubtful help; splenectomy is contraindicated. The prognosis is guarded.

## DISTURBANCES OF THE MECHANISM FOR CLOTTING

See also page 253.

### THE HEMOPHILIAS

Hemophilia can no longer be considered a single disease entity; it should be recognized as a syndrome representing several distinct inborn errors of metabolism. Hemophilic states are now identified as being due to defects in any of several substances necessary for thromboplastic activity. The major ones are the antihemophilic globulin (AHG, thromboplastinogen, plasma thromboplastin factor), plasma thromboplastin component (PTC) and plasma thromboplastin antecedent (PTA). The clinical conditions associated with deficiencies in these substances are now termed hemophilias A, B and C, respectively.

Clinical states resembling these more common forms of hemophilia are known, which involve faulty generation of thromboplastin, but in which no deficiency of AHG, PTC or PTA can be found. Lack of other plasma factors is presumed, each factor generally being named after the patient in whom the rare defect was first found, e.g., Hageman factor and Stuart factor.

Defects in the formation or activity of prothrombin (p. 980) or fibrinogen (p. 982) may also give rise to hemorrhagic tendencies with prolonged coagulation and normal bleeding times, but the associated clinical states are not classified with the hemophilias.

All the hemophilias are characterized by an unusual tendency to bleed both externally and into tissues, and particularly into joint spaces, after minimal or no trauma. The coagulation time is usually prolonged, the

bleeding and prothrombin times being normal.

#### HEMOPHILIA A

(TRUE OR CLASSIC HEMOPHILIA, AHG DEFICIENCY)

Hemophilia A occurs in all races and is inherited as a sex-linked recessive trait, occurring almost exclusively in males. The extremely rare exception of the disease in a female may occur when an affected male weds a female carrier. The male hemophiliac is a "bleeder" and has a demonstrable inability to produce antihemophilic globulin (AHG) in adequate amounts. Though it may be shown that the female carrier has less than normal levels of AHG in her plasma, only rarely does she have a mild bleeding tendency.

**Clinical Manifestations.** Clinical symptoms may occur within the first few days after birth in the form of hemorrhage from the umbilical cord or following circumcision, either of which may threaten life. Otherwise, excessive bleeding is not likely to occur until the infant begins to walk. Then a tendency to excessive bruising may be encountered, with large hematomas at the sites of minor trauma. External hemorrhage at this time is most often the result of trauma to the mouth or nose. In older children uncontrollable bleeding following extraction of teeth or removal of tonsils may be the first serious sign of hemophilia. Bleeding may involve the liver, spleen, pleural or peritoneal cavities, urinary tract, gastrointestinal tract or central nervous system. Death may result from intracranial bleeding, from exsanguination or from interstitial hemorrhage into the tissues of

the neck, resulting in respiratory obstruction.

Hemarthrosis is a characteristic lesion of hemophilia. It may occur early in life, but usually occurs first when the child begins to walk. Ankles, knees and elbows are particularly likely to become involved, but any joint may be affected. Painful swelling and severe discomfort accompany hemorrhage and may prohibit walking for days or weeks. Hemorrhage may also occur into the juxta-articular bone. Initially the hemorrhage is readily absorbed, but after repeated hemorrhages some fluid remains in the joint. Chronic inflammatory and degenerative changes occur which limit motion and may lead to eventual fixation of the joint. In late childhood or early adult life the large, tender, fixed joint is common in the hemophiliac.

**Laboratory Data.** The defect in coagulation is usually indicated by a prolongation of the clotting time. The prothrombin time and bleeding time are normal. The prothrombin consumption test, which reveals excessive residual prothrombic activity in serum after coagulation has taken place, demonstrates that the defect is in inadequate activation of thromboplastin. This test is more reliable than the clotting time, which may often be within the wide range of normal limits.

The thromboplastin generation test (p. 972) may be even more sensitive. That the defect in thromboplastic activation is actually due to absence of AHG may also be shown by "mixing" tests. The diagnosis is established if normal fresh plasma (in a 1:10 mixture with the patient's plasma) corrects the defect, and fresh plasma from a patient with proved hemophilia A does not correct it. The mixing test may occasionally be disturbed by the presence of an anticoagulant (antithromboplastic) substance in the blood of the patient with hemophilia A. This may be detected by showing that the plasma of the hemophilic patient in a 1:10 mixture disturbs the coagulation of normal blood or plasma.

Other studies of the blood are not diagnostic. Anemia, mild leukocytosis and moderate elevation in platelets may occur if loss of blood has been significant.

Roentgenograms of involved joints initially show the joint cavity to be distended, and there may be evidence of acute synovitis. After several hemorrhages into a joint there will be areas of subchondral erosion, with demineralization of epiphysal bone. Varying degrees of synovial thickening and contracture eventually occur. With repeated hemorrhages increased vascularization of the joint

space may lead to acceleration of bone growth and the premature appearance of centers of ossification. The articular surfaces may ultimately be completely destroyed. Juxta-articular cysts may develop as an aftermath of intraosseous hemorrhage at the epiphysal line and may erode into the joint space.

**Differential Diagnosis.** The family history may establish the typical pattern of recessive sex-linked inheritance. Since, however, female carriers may transmit hemophilia A for many generations without affected sons, and since new mutations appear to occur rather frequently, sporadic cases number as many as 30 per cent.

Hemophilia A can be differentiated from hemophilia B and hemophilia C by proper "mixing" tests, using the bloods of persons with known defects or through differential use of the thromboplastin generation test. The hemophilias can be separated from congenital hypoprothrombinemia and from parahemophilia by the prolongation of prothrombin time which occurs in the latter illnesses. Congenital afibrinogenemia is clinically indistinguishable from hemophilia, but shows incoagulability of the blood rather than simple prolongation of the clotting time, and a low level of fibrinogen may be demonstrated quantitatively. Certain platelet and vascular defects may occasionally be confused with the hemophilias, but they can be distinguished by abnormalities in the platelet count, clot retraction or tourniquet test.

**Course and Prognosis.** The hemophiliac lives under the constant threat of serious disability or death from his disease. Recurrent and ultimately crippling hemarthroses may progressively decrease the child's activities. Hospitalization is necessary more often for the younger patient than for the older child, whose periods of disability tend to become less frequent and may be of shorter duration. Occasionally a cyclic pattern may be manifest, in which periods with little or no bleeding as the result of moderately severe trauma will alternate with periods when severe hemorrhages appear to occur spontaneously. Infection often appears to accentuate the hemorrhagic tendency. Families in which the hemophilic members have a partial deficiency of AHG with a mild form of hemophilia have been recorded. In general it is impossible to prognosticate in early life the eventual degree of involvement.

**Treatment.** A major obligation is to help the patient and his family make the necessary adjustments in family and community life

that this disease imposes. A realistic picture must be presented to the parents, but they should know that many hemophiliacs live useful, active and productive lives. The joint efforts of physician and family should be directed toward preparing the child for a satisfactory role in adult life.

In early years responsibility for prevention of injury to the hemophiliac rests largely with the parents. The careful selection of toys, the padding of crib and playpen and intelligent supervision of play are important prophylactic measures. Sponge rubber pads over knees and buttocks may be helpful to the infant just learning to walk. At school age the boy should attend classes with normal children, but the understanding help of his teachers and classmates must be elicited. The older child becomes familiar with his limitations and, with guidance, seeks his proper level of activity among normal companions. Tolerable normal activity should not be denied, lest emotional crippling from overprotection be more disabling than the effects of repeated hemorrhages.

Since antihemophilic globulin loses its activity rapidly in blood stored in a fluid state, transfusion of *fresh* whole blood or plasma, or its equivalent, is essential for treatment of acute hemorrhage. Inasmuch as 10 to 20 per cent of the normal concentration of AHG must be present in the blood to assure adequate coagulation, fresh plasma should be given in the amount of 10 ml. per kilogram, at a rate of 1.5 to 2.0 ml. per minute, to initiate hemostasis. Further slower infusion must follow if hemostasis is to be maintained, at times for three to five days. When blood loss has been severe, rapid infusion of blood is necessary to restore blood volume and to relieve shock. When operation is necessary, fresh blood should be given for three to four hours prior to the operation and for seventy-two or more hours postoperatively.

In the frozen state fresh plasma loses its antihemophilic property slowly, and may be used effectively months after preparation for the control of hemorrhage in the hemophiliac. Frozen plasma has the additional advantage that the danger of sensitization to red blood cell antigens is minimized for children who are likely to receive multiple transfusions. Cohn's fraction I of plasma, which contains AHG in addition to fibrinogen, produces effective control of bleeding in the hemophiliac, but the material must be prepared from *fresh* blood plasma, is expensive, and is likely to transmit serum hepatitis if pre-

pared from pooled plasma. A lyophilized concentrate of fresh plasma is available (Anti-hemophiliac Plasma, Hyland Laboratories) and has been found helpful.

The appearance of an anticoagulant substance in the blood of the hemophilic patient is a serious complication of therapy, since subsequent administration of fresh plasma or blood may be much less effective in the control of hemorrhage. These substances are found in the pseudoglobulin fraction of plasma and counteract the effect of AHG through antithromboplastic activity. Van Creveld has found that ACTH may temporarily depress these abnormal substances and permit more effective action of fresh plasma or blood. Since repeated infusions of blood and plasma are thought to predispose to the development of anticoagulants, local measures for the control of hemorrhage should be tried whenever reasonable before the use of plasma or blood is considered.

Any wound should be thoroughly cleansed, and any foreign matter, including clotted material, should be removed. Powdered thrombin may then be applied to the injured area, although, if the lesion is extensive, topical application will often have little effect. Judicious local pressure should also be applied when possible, and cold applications to the traumatized area may reduce bleeding through vasoconstriction. Closure of a wound by sutures should be avoided whenever possible, since even this mild trauma may aggravate hemorrhage. Local application of epinephrine solution sometimes aids in hemostasis, but astringents and styptics usually do more harm than good.

The control of hemorrhage into joint cavities is extremely important if prolonged or lasting disability is to be prevented. Ice bags should be applied immediately, and the involved joint wrapped in an elastic bandage. Parents of children prone to develop hemarthroses should keep one or two plastic icebags in the refrigerator at all times for immediate use if hemorrhage occurs. This local therapy should be continued for at least forty-eight hours if the hemorrhage is controlled; if it is not promptly controlled, a transfusion of plasma should be given. After bleeding has been controlled for forty-eight hours or longer, cautious application of heat will aid in absorption of the fluid in the joint cavity. This is followed by gentle passive exercise and massage. With such attention much chronic disability may be avoided. When ultimate fixation of a joint seems in-

evitable, an effort should be made to ensure fixation in a position as functionally effective as possible. Results of injecting hyaluronidase into recently affected joints have been disappointing.

### HEMOPHILIA B

(PTC DEFICIENCY, CHRISTMAS FACTOR DEFICIENCY)

The hemophilic state due to deficiency of plasma thromboplastin component (PTC) is responsible for about 15 per cent of all patients with hemophilia. It is inherited as a sex-linked recessive trait; so far it has been reported only in males.

The clinical manifestations, course and prognosis of hemophilia B do not in any way differentiate it from hemophilia A. The clotting abnormality is typical of the hemophilic state: the clotting time is prolonged, or occasionally normal; prothrombin consumption is abnormal, owing to inadequate activation of thromboplastin. The plasma of the patient with hemophilia B readily corrects, *in vitro*, the coagulation defect in the plasma of patients with hemophilia A or C, and vice versa.

PTC is relatively stable in stored blood or plasma, so that the patient with hemophilia B can be effectively treated by the infusion of *stored* blood or plasma, whereas only *fresh* blood or plasma is effective in hemophilia A; otherwise therapy is similar for both hemophilias A and B.

### HEMOPHILIA C

(PTA DEFICIENCY)

Hemophilia C is the result of a defect in the synthesis of plasma thromboplastin antecedent (PTA). The abnormality is inherited as a mendelian dominant trait and therefore affects males and females alike. No sporadic cases have been reported to date.

The hemorrhagic tendency is not so great as in hemophilias A and B. It may appear within the first few hours of life and is manifest as a tendency to bleed excessively from mild trauma or laceration. Loss of blood following dental extraction or tonsillectomy may be especially prominent. Hemarthrosis apparently does not occur.

The clotting time in hemophilia C may be prolonged or within normal limits. The defect in utilization of prothrombin is readily demonstrated by the prothrombin consumption test. Plasma from patients with PTA defi-

ciency readily corrects the clotting defect in the bloods of patients with hemophilias A and B, and vice versa.

Therapy in hemophilia C is similar to that of hemophilias A and B. Although bleeding is generally less severe, the need for treatment may be just as urgent. Since PTA is relatively stable, the clotting defect in hemophilia C can be corrected by the use of stored blood or serum.

### VON WILLEBRAND'S SYNDROME

(VASCULAR HEMOPHILIA OR PSEUDOHEMOPHILIA)

Von Willebrand described many years ago a familial hemorrhagic disorder characterized by prolonged bleeding time with normal coagulation time. The syndrome closely resembles hemophilia A; there are massive hematomas in infancy, and hemarthroses, epistaxes and bleeding following dental extractions in subsequent years. Genetic transmission is as a mendelian dominant, affecting both sexes.

Recent evidence indicates that at least two groups of patients can be identified who present the clinical findings and genetic pattern of von Willebrand's disease. In the first group a vascular abnormality identified by capillary microscopy is the only demonstrable factor contributing to deficient hemostasis. Except for prolonged bleeding time there is no other abnormality in coagulation. In the second group the clinical pattern is similar with an identical vascular abnormality, but there is, in addition, a variable degree of deficiency of antihemophilic globulin. In patients of this second group infusion of plasma containing AHG corrects the hemostatic defect both clinically and *in vitro*. The deficiency of AHG is not so severe as in hemophilia A and is often detected only by the thromboplastin generation test. The clotting time and prothrombin consumption may be normal.

Schulman and his co-workers, who first differentiated the two groups of patients with von Willebrand's syndrome, have suggested that the condition with both vascular defect and AHG deficiency be termed *vascular hemophilia*, and the condition with isolated vascular defect be called *pseudohemophilia*.

### DEFICIENCIES IN PROTHROMBIN AND ACCESSORY FACTORS

Prothrombin is converted to thrombin through the actions of activated thrombo-

plastin in the presence of ionized calcium and of the stable and labile accelerator factors. Deficiencies of these substances may arise from faulty production or faulty utilization when abnormal antifactors are elaborated against them. Congenital defects in synthesis are known for each of these factors. Vitamin K is necessary for the synthesis of prothrombin and stable factor. Since all three substances are formed in large part in the liver, in far advanced hepatic disease clinical deficiencies may occur involving one or all factors.

Deficiencies in prothrombin or related substances are manifest clinically as more than usual hemorrhage from slight trauma or surgical incisions. Epistaxis, hematuria, gastrointestinal and intracranial hemorrhages and extensive hematomas occasionally occur, but hemarthroses are rare.

Only when deficiencies of prothrombin factors are unusually marked is the defect in coagulation shown by a prolongation of the clotting time. The one-stage prothrombin time (Quick), however, is always prolonged, regardless of whether the defect is in prothrombin or in an accelerator factor; the prothrombin consumption test has no practical advantages. The platelet count, fibrinogen level, tourniquet test, bleeding time and thromboplastin generation test are normal in patients with defects in the prothrombin complex.

#### DEFICIENCY OF PROTHROMBIN

The synthesis of prothrombin depends upon adequate hepatic function and an adequate supply of vitamin K. Defects in either will lead to hypoprothrombinemia.

**Hypoprothrombinemia in the Newborn.** In most newborn infants the one-stage prothrombin time is considerably prolonged within a few hours after birth; it reaches a maximum prolongation by about three days, and rises to normal levels gradually within five to ten days. The defect in neonatal prothrombin activity is due to defects of both prothrombin and stable factor, which apparently depend upon a transient deficiency in available vitamin K. Administration of this vitamin produces a prompt increase in plasma. Whether hypoprothrombinemia of the newborn is in small or large measure responsible for *hemorrhagic disease of the newborn* is not clearly established.

**Congenital Defect in the Synthesis of Prothrombin.** Several instances have been

reported in which there appeared to be a congenital absence of prothrombin production. These reports are difficult to evaluate, since defects in stable or labile factors were not excluded. There is no reason, however, to expect that congenital defects in synthesis of prothrombin may not occur.

**Hypoprothrombinemia Due to Avitaminosis K** (see p. 379).

**Hypoprothrombinemia with Severe Hepatic Disease.** In a number of conditions in which hepatic parenchyma is severely injured the synthesis of prothrombin may be primarily disturbed, so that there is no response to parenteral administration of vitamin K. There are usually deficiencies of other coagulation factors, such as of fibrinogen and stable and labile factors, which contribute to the severe hemorrhagic state which accompanies hepatic failure.

#### DEFICIENCIES IN STABLE FACTOR

Since both stable factor and prothrombin are formed in the liver and need vitamin K for their synthesis, acquired deficiencies in these substances usually occur together. Several instances of isolated deficiency of stable factor have been reported, however, in which the defect is genetic. The affected patients have shown a tendency to excessive bleeding in early life, with recurrent epistaxis, excessive bruising, subarachnoid hemorrhage and melena, and later menorrhagia. Owren reported a family in which the defect was inherited as a dominant trait of uncertain penetrance. Decreased activity of stable factor was found in many maternal relatives, but only those with less than 10 per cent of normal activity had evident hemorrhagic tendencies.

The *diagnosis* of congenital stable factor deficiency may be established by appropriate "mixing" tests, using the fresh and stored bloods of persons with known defects in coagulation. The prothrombin time is prolonged, but the clotting time may be normal even when the deficiency is severe. Vitamin K does not alter the defect, but the disturbance may be temporarily relieved by transfusion of stored blood or plasma.

#### DEFICIENCIES IN LABILE FACTOR

Low levels of labile factor activity have been found in patients with severe hepatic disease, in acute leukemia, in postoperative states and in the late stages of cancer. The activity of labile factor is normally present in the neonatal period.

Deficiencies of labile factor may occur as congenital defects in synthesis, which may be inherited as a mendelian dominant trait (parahemophilia, Owren's disease). *Parahemophilia* affects both sexes and may be responsible for a hemorrhagic disorder of moderate severity from early life. Excessive subcutaneous bleeding, recurrent epistaxis, profuse menorrhagia and severe hemorrhage following dental extractions and other surgical procedures have been recorded.

There are only moderate prolongations of the one-stage prothrombin time and the clotting time. The deficiency is corrected by small amounts of *fresh* plasma or blood.

## DISORDERS INVOLVING FIBRINOGEN AND FIBRIN

Mention has been made of the hypofibrinogenemia which may accompany severe diseases of hepatic parenchyma. Other rare disorders of clotting closely related to the formation or utilization of fibrinogen or fibrin include congenital afibrinogenemia and the hemorrhagic disorders associated with fibrinolysins.

### CONGENITAL AFIBRINOGENEMIA

Congenital afibrinogenemia is a rare hereditary defect in the synthesis of fibrinogen, affecting both sexes and probably due to an autosomal recessive gene; consanguinity has been frequently noted in the parents of affected children.

Hemorrhagic manifestations commonly make their appearance in the neonatal period. Clinically the disorder is indistinguishable from hemophilia; the blood, however, instead of clotting only after a prolonged time, proves to be absolutely incoagulable after many hours or days, and no fibrin deposit is produced in plasma on heating it at 56° C. for twenty minutes. The latter is a quick and simple test for afibrinogenemia. The sedimentation rate of the erythrocytes is exceptionally slow.

Specific *treatment* is limited to transfusions of whole blood, plasma or concentrated fibrinogen (Cohn fraction I). Therapy should be planned to maintain the blood level of fibrinogen at 60 mg. per 100 ml. or higher. Injections may be given according to need, or prophylactically at intervals of three to four weeks. Supportive management in other respects resembles that suggested for hemophilia.

## A HEMORRHAGIC DISORDER DUE TO FIBRINOLYSINS

### (FIBRINOLYTIC PURPURA)

Normal plasma contains a fibrinolytic enzyme, usually in an inactive form (profibrinolysin). The mechanism of activation of profibrinolysin to fibrinolysin is not known; it is postulated that activation occurs through a fibrinolysokinase related to, if not identical with, streptokinase. Apparently many tissues normally contain an inhibitor of fibrinolysokinase (antifibrinolysokinase), which exerts control over activation of profibrinolysin.

A hemorrhagic disorder caused by excessive activation of fibrinolysin has been identified in a variety of clinical conditions, though rarely in children. Trauma, hemorrhage and shock are recognized as potential initiators of excessive fibrinolysis. The lungs and uterus contain the highest concentrations of fibrinolysokinase, which may explain why bleeding disorders due to fibrinolysins have been most commonly encountered as complications of pulmonary and gynecologic surgery and in certain disorders of the placenta. Excessive fibrinolysis may also cause severe hemorrhage in leukemia, severe bacterial infections or cyanotic congenital heart disease or in association with a variety of malignant neoplasms. Excessive fibrinolysis in such unrelated diseases is not accounted for by any single factor.

Bleeding associated with excessive fibrinolysis is usually severe and difficult to control, and may begin at a number of sites without apparent provocation. Detection of excessive fibrinolysis is ordinarily not difficult; the blood will usually clot readily enough, but if a sterile sample of clotted blood is incubated at 37° C., the clot will disappear within twenty-four hours. The degree of abnormal activity is inversely proportional to the time required for dissolution of the clot.

*Therapy* may be urgently needed and has two aims: to correct the faulty excessive activation of fibrinolysin and to replace clotting proteins being destroyed in the process. Replacement of blood may also be urgently needed. The replacement of clotting proteins can best be accomplished by the liberal administration of concentrated fibrinogen (Cohn's fraction I) or large amounts of plasma; fraction I is the more effective. Cortisone has appeared to be effective in reducing the activity of fibrinolysin.

# The Spleen

The diversified functions of the spleen include activities related to its lymphoid tissue (antibody formation and other mechanisms of defense), to its reticuloendothelial tissue (removal of degenerating blood cells) and to its unique circulatory structure (storage, sequestration and destruction of blood cells).

The parenchyma is made up of two distinct types of tissue: the lymphoid follicles (malpighian corpuscles) and the splenic pulp, which consists of reticuloendothelial tissue containing erythrocytes and other blood cells. The lymphoid follicles surround small arteries and share in alterations of the lymphoid tissue of the body such as occur in leukemia, tuberculosis, sarcoidosis, infectious mononucleosis and less specific infections. The reticuloendothelial elements of the splenic pulp share with similar tissue elsewhere the pathologic deposition of lipid material in Gaucher's disease, Niemann-Pick disease, and the like, and are typically altered in nonlipid reticuloendotheliosis (Letterer-Siwe disease). The splenic pulp has vascular arrangements found nowhere else in the body, consisting of arterioles and venules, the pulp spaces and the venous sinuses. The pulp spaces are large open channels which wander among cords of reticular tissue and contain an abundance of reticuloendothelial elements, including many motile phagocytes. Blood apparently passes from the arterioles either into the pulp spaces, where it is brought into contact with these scavenger cells, or directly into the venous sinuses. An "open" and a "closed" circulation appear to coexist. Plasma is relatively easily lost from the pulp spaces, leaving a high concentration of cells which then enter the venous sinuses through a unique arrangement of slitlike openings. The length of time during which the cells are held in the spleen is dependent upon the ease with which they can pass through these openings and upon the contractile capacity of the organ. Structurally or metabolically abnormal erythrocytes have difficulty in traversing this complicated pathway, and stasis and destruction occur in the vascular spaces.

The spleen appears to have some control over the production and release of blood cells from marrow. Its removal is associated with the appearance of immature erythrocytes in peripheral blood, with granulocytic leukocytosis and with increased numbers of platelets in the circulation. In animals as little as 10 per cent of residual spleen inhibits such changes. These changes are transient; within a few days most splenic functions are assumed by other tissues. An unusual susceptibility to overwhelming or recurrent severe infection appears to follow splenectomy in some instances.

The spleen is an important source of new blood cells in some vertebrates and in the human fetus, but not after birth in man. Blood storage, against sudden increases in the demand for blood, is an important function of the spleen in many vertebrates, but is of minor importance in man.

With shielding of the spleen or with injection of homogenates of spleen, animals survive otherwise lethal doses of radiation. The demonstration by Lindsley that heterologous splenic cells survive and multiply when injected into the radiated animal implies that actual seeding of splenic cells exerts the protective influence. Human experience with this property of the spleen is not available.

**Clinical Evaluation of the Spleen.** On occasion the spleen can be felt at or slightly below the costal margin in apparently healthy infants and children. Light or superficial palpation is more apt to be effective in locating the organ than deep palpation, particularly if the supine infant is turned slightly toward his right side and the finger tips are lightly pushed toward the costal margin during inspiration. Since the spleen must be enlarged to about three times its usual size before it becomes palpable, the possibility of a pathologic disturbance should be considered whenever it is felt. The ease with which it can be felt depends upon a number of factors. Unusual depression of the diaphragm may displace a normal spleen downward, or displacement of abdominal contents upward may

make it impossible to feel a significantly enlarged spleen.

If a question arises about a mass in the left upper quadrant, the following considerations may be helpful: (1) the upper margin of the spleen is almost always concealed by the ribs; (2) the splenic notch may usually be identified; and (3) intestines do not cover the spleen, as they do renal or other retroperitoneal tumors.

At birth the weight of the spleen is about 10 gm.; at one year, about 30 gm.; at five years, about 40 to 50 gm.; at puberty, about 80 gm.; and at maturity, about 150 to 190 gm.

**Anomalies.** Congenital absence of the spleen is rare, occurring at times with cardiac and other congenital defects, especially situs inversus. Blood findings resemble those in patients with splenectomy: leukocytosis, siderocytosis, decreased osmotic fragility of red blood cells and mild normoblastemia. Some susceptibility to infection may be present; an isolated instance is known of repeated attacks of sepsis in asplenia.

Unusually small as well as large spleens are occasionally observed in infants without demonstrable cause or relation to function.

Various anomalies of shape have been recorded, among them an unusual elongation of the organ and an increased number of notches on the ventrocaudal margin.

When there is a complete transposition of the abdominal viscera, the spleen is on the right side. Elongation of the splenic pedicle permits descent of the spleen to a lower level than usual, so-called *splenoptosis*.

Supernumerary spleens are not rare and may undergo hyperplasia after removal of the principal splenic structure. They are usually located in the region of the splenic pedicle, but may be widely scattered, occasionally being in the scrotum, usually on the left side; a testicular tumor may be suspected.

**Rupture of the Spleen.** Traumatic rupture of the spleen may occur from a sharp blow to the left flank, as, for example, in automobile accidents, from a direct blow or from striking a projecting object while running, sledding, bicycling or the like.

The symptoms vary, but there are usually some or all of the following: vomiting; abdominal pain, which may not be located in the left flank; muscle spasm, tenderness and fullness in the left flank; shoulder pain, especially in the area of the left scapula; and shock. A complaint of thirst is not unusual. There is no correlation between the external

manifestations and the extent of the damage to the spleen. An increase in the pulse rate, a decline in the systolic blood pressure and an increase in the number of leukocytes, especially neutrophils, are strongly suggestive of active internal hemorrhage. Later, the decrease in the number of erythrocytes in the peripheral blood will become manifest. The lesion following injury to the spleen may be a subcapsular hematoma, which may rupture with resultant fatal hemorrhage several days after the initial injury.

When other trauma is not too extensive, removal of the spleen, as soon as adequate treatment for shock has been instituted, offers the greatest possibility for recovery. There is usually no effect upon the subsequent growth and development of the child. Occasionally the peritoneal cavity will be "seeded" by implantation of splenic fragments; intestinal obstruction may result.

Rupture of a pathologic spleen is more likely to occur than that of a normal one, and may be either spontaneous or traumatic. In the child such rupture most commonly occurs in infectious mononucleosis. In the newborn infant splenic rupture may occur in severe hemolytic disease.

**Splenomegaly in Disease.** Enlargement of the spleen may result from increase in its vascular, lymphoid or reticuloendothelial elements. The more common conditions which may be accompanied by clinical splenomegaly are listed in Table 104.

## CONGESTIVE SPLENOMEGALY

### (SPLENOPORTAL HYPERTENSION, BANTI'S SYNDROME)

In 1893 Banti described a syndrome of anemia, leukopenia, thrombocytopenia and unexplained splenomegaly, in which, as the disease progressed, the liver became enlarged and ascites and other evidence of portal cirrhosis became manifest. Death occurred as a result of hepatic insufficiency or gastrointestinal hemorrhage. Banti interpreted the disturbance as a primary one of the spleen. The syndrome is now considered to result from obstruction of the splenic venous system. Primary disturbances may be located in the liver, in the extrahepatic portal vessels or in the splenic vein.

Portal cirrhosis is the most common primary condition responsible for congestive splenomegaly. It is rare in childhood. In the Near and Far East the hepatic lesions of schistosomiasis commonly produce porto-

splenic venous hypertension and congestive splenomegaly ("Egyptian spleen"), but in the United States and western Europe the most common cause of congestive splenomegaly in children is extrahepatic vascular obstruction, usually inflammatory, which involves the portal or splenic vein, or both. Such thrombophlebitis most commonly follows omphalitis or generalized infection in early life. Neoplasms, especially pancreatic, and post-traumatic strictures of the splenic or portal veins are rare causes of congestive splenomegaly. There are at least three recorded instances of congestive splenomegaly in more than one member of a family.

**Pathology.** When persistent and severe venous hypertension leads to enlargement of the spleen, there are increases in reticular and fibrous tissues, which encroach upon the vascular spaces. The original pulp spaces become reduced to rigid channels lined with endothelium and communicate directly with venous sinuses rather than through the normal slitlike openings. The latter become occluded; and the splenic circulation eventually becomes a closed one similar to that elsewhere in the body. The circulation of blood cells becomes retarded, and deficits in erythrocytes, leukocytes and platelets in the peripheral blood accompany these alterations for some unexplained reason.

**Clinical Manifestations.** The age at onset of congestive splenomegaly varies with the primary disturbance. The onset may be insidious, splenomegaly being noted in early infancy and progressive enlargement and mild anemia developing over a period of months or years. Recurrent bouts of diarrhea may occur, and epistaxis is not uncommon. The older child may complain of a feeling of fullness or pain in the left upper quadrant. Unless splenectomy is performed, the spleen continues to enlarge and may attain enormous size.

In more than half of the patients gastrointestinal hemorrhage ultimately becomes the predominant problem. Loss of blood may be microscopic or massive, leading rapidly to death, and may arise from the upper or the lower part of the gastrointestinal tract. It may be the first event calling attention to portosplenic hypertension. There may be other signs of portal obstruction, such as extensive collateral circulation, particularly in advanced cases. Excessive bruising and recurrent epistaxis occur when significant thrombopenia develops.

**Laboratory Data.** Early in congestive

splenomegaly there are few, if any, abnormalities in the peripheral blood. As splenomegaly becomes marked, a leukopenia develops with counts as low as 1800 cells per cubic millimeter; there is a relative lymphocytosis. The platelet count is reduced to 100,000 to 160,000 per cubic millimeter, and anemia is almost always present. It may be normochromic in response to sudden loss of blood or hypochromic and microcytic in response to a deficiency of iron secondary to chronic loss of blood. Anemia may also result from excessive destruction of erythrocytes within the enlarged spleen (secondary hypersplenism),

Abscess
Metastatic neoplasm (rare)

in which case the anemia will be normochromic and normocytic with moderate reticulocytosis.

The bone marrow is normal or hyperplastic in respect to erythroid elements.

If hepatic disease with intrahepatic portal obstruction is responsible for congestive splenomegaly, abnormalities of hepatic function will be demonstrable. If portal hypertension is present, esophageal varices may ultimately be shown roentgenographically.

It is possible, with splenic puncture, to obtain a measurement of intrasplenic pressure indicative of pressure in the splenic vein. At the same time material may be aspirated for microscopic study, and a radiopaque medium injected for splenic venography. Such procedures should be done only with the opportunity immediately at hand for blood transfusion and necessary or definitive surgery.

**Prognosis.** The prognosis is dependent upon the origin of congestive splenomegaly. A localized obstruction of the splenic vein or portal system may be remedied by direct surgical means or by creation of a shunt to bypass the obstruction. If the original difficulty lies within the hepatic parenchyma, the outlook for full recovery is guarded, but many years of symptomatic relief may follow surgical diversion of the portal hepatic flow into the renal vein or the vena cava. In a few instances, after years of hemorrhagic manifestations, some decrease in bleeding may result from establishment of extensive collateral circulation to the portal vein. If surgical therapy is not possible, congestive splenomegaly eventuates in death from severe bleeding or hepatic failure.

**Diagnosis.** The diagnosis can be made only after exclusion of other conditions responsible for anemia, leukopenia, thrombocytopenia and splenomegaly. If the onset is in early life, there may be a history of omphalitis or sepsis, or a history of trauma to the upper abdomen may suggest the diagnosis in an older child. The peripheral blood and bone marrow must be carefully studied to exclude leukemias, aplastic anemias and Gaucher's disease, Niemann-Pick disease or other reticuloendothelioses. Tuberculosis, sarcoidosis and other chronic infections must also be excluded.

**Treatment.** The site and cause of vascular obstruction must be established as accurately as possible. When vascular obstruction is limited to the splenic vein, splenectomy will be curative. More commonly when larger portions of the portosplenic venous system are

involved or the obstruction is the result of intrahepatic abnormality, therapy is directed, if possible, at relief of the portal hypertension with the hope of postponing or averting hepatic failure or serious gastrointestinal hemorrhage. Splenectomy alone is rarely indicated and removes the possibility of using this vein in the creation of a vascular shunt. A splenorenal anastomosis is indicated when the point of obstruction is within the liver or between the liver and the point of entry of the splenic vein into the portal vein. If a splenorenal shunt is beyond present or future consideration, splenectomy *may* be helpful, since the blood contributed to the portal stream through the spleen is eliminated.

When the child reaches the age of eight to ten years, a portacaval shunt may be feasible. On occasion, however, if the child has not succumbed to hepatic failure or hemorrhage, the development of collateral circulation may have been adequate to have eliminated need for surgical intervention.

The course of this disease may be long and trying. The family must be aware of the signs and dangers of gastrointestinal hemorrhage. Temporary and sometimes lifesaving relief of esophageal bleeding may be obtained through emergency use of special balloons for tamponade which should be kept in readiness at home. The child is taught to swallow them; they are then inflated when at the point of probable hemorrhage. The procedure may control bleeding until transfusion therapy can be arranged.

Anemia from loss of blood may require iron therapy. Supportive measures for the relief of any hepatic disorder should be used.

## SPLENIC CYTOPENIA

### (HYPERSPLENISM)

Doan and his co-workers have described two blood dyscrasias often associated with some degree of splenomegaly in which they believe the basic disorder to be in the spleen. These are primary splenic neutropenia and splenic panhematopenia. It is postulated that in these diseases the spleen exercises a pathologic sequestration and destruction of formed elements of the blood, as it is presumed to do selectively in hereditary spherocytosis for erythrocytes and in primary thrombopenic purpura for platelets.

### PRIMARY SPLENIC NEUTROPENIA

This syndrome is an acute or chronic granulopenia presumed to be due to excessive de-

struction of neutrophils by the spleen (see also p. 965). The spleen may or may not be palpable. There is a myeloid hyperplasia in the bone marrow and active phagocytosis of large numbers of neutrophils in the spleen by macrophages. These factors, with the low white cell count in the peripheral blood, suggest that normal neutrophils are destroyed by an abnormally functioning spleen or that some abnormality in the granulocytes accounts for their destruction by the spleen. The course of splenic neutropenia may be characterized by exacerbations and remissions. During the active phase there may be fever, nausea, fatigue, and dull pain in the upper left abdominal quadrant. The total white blood cell count is usually 2000 to 3000 per cubic millimeter, but may be less than 1000, with almost complete absence of neutrophils. Splenectomy apparently controls the disease.

#### SPLENIC PANHEMATOPENIA

**Primary Type.** In this syndrome it is believed that there is an abnormal destruction of all cellular elements of the blood by the spleen. Dameshek has suggested that the abnormal action of the spleen may not be directly phagocytic, but that it may be due to an abnormal inhibiting effect of a splenic hormonal substance upon hematopoiesis in the bone marrow. The disease may apparently occur as a chronic relapsing or relatively acute condition.

Clinically, this syndrome simulates an aplastic anemia, owing to the reduction of the red and white cells and platelets in the blood. However, the marrow in primary splenic panhematopenia is hyperplastic in relation to all elements. Splenectomy may be effective.

**Secondary Type.** Splenic hematopenia may exist as a secondary factor in any condition in which there is extreme enlargement of the spleen, irrespective of the cause. Presumably the anemia, leukopenia and thrombopenia may result because the bone marrow, in spite of hyperactivity, is unable to compensate.

**Treatment.** Splenectomy is often effective in the treatment of the various splenic cytopenias. Failures have been attributed to (1) the presence of one or more remaining accessory spleens; (2) the presence of generalized reticuloendothelial hyperplasia (in such a case splenectomy would result in removal of only a small part of the offending reticuloendothelial system); or (3) failure to ascertain that the bone marrow is not primarily

at fault. Evidence of myelophthisis, hypoplasia, or toxic depression of the bone marrow must be excluded by study of the marrow before splenectomy.

Splenectomy may be considered in hypersplenism associated with thalassemia major, chronic myelocytic leukemia, Gaucher's disease and chronic lymphomas; it may be responsible for sufficient clinical improvement and prolongation of life to be justified even in a condition which is eventually fatal.

#### INFARCTION OF THE SPLEEN

Infarction of the spleen in children is rare. It has been encountered in such generalized, primarily vascular disorders as polyarteritis nodosa, thrombotic thrombocytopenia, and the like, and is a possibility in persons with sickle cell trait who travel by air. The onset is sudden, with abdominal pain in the left upper quadrant. Splenectomy has been the usual treatment; more conservative management has been suggested.

# The Lymphatic System

The lymph vessels begin as small capillaries in the intercellular spaces of the body. These capillaries unite to form larger vessels, which join in turn to form the large lymphatic ducts which enter the subclavian veins. Tissue masses (lymph nodes and lymph nodules) are associated with this system of vessels and interrupt it in many regions. The lymph which the vessels contain is a clear, colorless fluid similar in composition to intercellular fluid except for protein content, which is about midway between that of blood serum and of interstitial fluid. As a result of the valvular construction and contractile activity of lymph vessels, lymph flows through the vessels to the lymph nodes, where it is filtered through extensive channels of reticuloendothelial tissue and again enters lymph vessels to end in the venous return to the heart.

Lymph nodes are important elements in defenses of the body against infection; they immobilize toxins of large molecular weight as well as infectious organisms. Damage by entrapped bacteria may occur, but must be extensive before the efficiency of the filter becomes so reduced that organisms pass the barrier. Lymph nodes are widely distributed, but are abundant about the large joints (popliteal spaces, inguinal areas, axillas, epitrochlear regions), in the mediastinum, retroperitoneal area and mesentery, and in the cervical region, where they filter the lymph from the upper respiratory tract and scalp.

In addition to the encapsulated lymph nodes, there are less sharply delineated and smaller collections of lymphoid tissue known as lymph nodules. These are found in the bone marrow, underlying the epithelium of

the gastrointestinal tract and in submucosal regions of the upper respiratory tract, particularly in the nasopharynx.

Besides their filtering and phagocytic actions, the lymph tissues serve as important sites of antibody production. The active germinal centers of both nodes and nodules are the chief site of production of the lymphocytes of the peripheral blood and, to a less degree, of the monocytes.

The growth of lymphoid tissue follows a pattern unlike that of other tissues. Small in amount at birth and in early life, lymphoid tissue increases rapidly during early childhood, reaches adult size by about six years and exceeds adult size from that time until puberty, when striking atrophy occurs. The actual number of nodes increases about three times in this same period. It is suggested that changes in endocrine activity are primarily responsible for the lympholysis that occurs with puberty, particularly maturation of adrenal cortical function.

During infancy and early childhood, lymphoid tissue characteristically responds to infection by rapid and excessive swelling and hyperplasia, which may last long after the primary infection which caused it has disappeared. Lymph nodes around the respiratory tract, from the tonsillar region to the mediastinum, are more frequently involved than those in other areas. Involvement of the mesenteric lymph nodes is also common. Occasionally a node or a group of nodes may harbor infection long after the original site has been cleared. Thus lymph nodes, when diseased, may be a hazard rather than a safeguard.

## DISEASES OF THE LYMPH VESSELS

*Acute lymphangitis* is a part of the local lesion of acute cellulitis; involvement of the lymph vessels and the regional lymph nodes draining an infected area is also a common accompaniment of other infectious lesions.

The inflamed superficial lymph vessels can often be seen in the skin radiating toward the regional lymph nodes.

Diffuse chronic or persistent *lymphedema* (elephantiasis) is a rare condition except in

tropical countries, where it is mainly due to the lymphangitis of filariasis (p. 588). Persistent lymphedema resulting from lymphangitis of nonparasitic origin is extremely infrequent in childhood. Localized lymphedema may result from obstruction by lymphangiomas (p. 1359) or other tumors, from surgical removal of lymph nodes or the effects of irradiation.

*Congenital lymphedema*, or elephantiasis, known as *Milroy's disease*, is limited to one or both lower extremities and apparently is usually genetically determined. The lymphedema is permanent, pits on pressure, and the limb is painless (Fig. 306). Milroy's disease may be manifest at birth or may appear later in childhood. Some cases of hemihypertrophy have been attributed to congenital lymphedema.

Chylous ascites and chylothorax are discussed on pages 686 and 818, respectively.

**Tumors of Lymph Vessels.** See page 1359.

FIG. 306. Milroy's disease in a boy 8 years of age, the swelling of the left leg having been present for at least 4 years.

## DISEASES OF THE LYMPH NODES

Generalized enlargement of lymph nodes encountered in the neonatal period suggests congenital syphilis, generalized cytomegalic inclusion disease, toxoplasmosis or widespread bacterial sepsis. Subsequently generalized enlargement points most likely to infectious mononucleosis, leukemia, Hodgkin's disease or metastatic tumor. Mild degrees of generalized enlargement occur with many infectious processes, such as measles, German measles, mumps, scarlet fever, tularemia, typhoid fever and infectious lymphocytosis. A mild degree of generalized adenopathy is occasionally encountered as an adventitious finding in a child who has no apparent illness.

Enlargement of a single node or a group of nodes is much more common than generalized adenopathy. Most often it results from an infection in its drainage area. Thus a scalp infection or nasopharyngitis will be responsible for involvement of cervical nodes, and intestinal infections of mesenteric ones. However, generalized diseases such as those mentioned above may initially or even throughout their course involve only a few nodes of one or more regions.

### LYMPHADENITIS

#### ACUTE LYMPHADENITIS

**Etiology.** An acute inflammation of the lymph nodes is produced by pathogenic or-

ganisms brought generally by the lymph stream from some focus of infection, or less commonly by the blood in septicemia. If the infection is localized, only a regional group of lymph nodes is inflamed, whereas in general sepsis there may be generalized lymphadenopathy. Bacterial toxins may also be a cause of lymphadenitis, as in the cervical swelling associated with diphtheria. Lymphadenopathy may also be associated with absorption of broken down tissue from an area of trauma, particularly with extensive subcutaneous or deep hemorrhage.

**Clinical Manifestations.** The amount of swelling of the lymph nodes tends to parallel the severity of the infection in the primary focus. Common examples are the cervical lymphadenitis associated with acute tonsillitis, the mediastinal involvement in bronchitis and bronchopneumonia, and the inguinal lymphadenitis in infections about the genitals and in the lower extremities. Occasionally the lymph nodes show greater involvement than the primary site; suppuration may then take place, and an abscess may develop. If the nodes are in a small space surrounded by structures which restrict enlargement, the pain may be excruciating. The skin overlying the affected nodes may be red, and cellulitis may be present. Spasm of adjacent muscles may cause pain on movements.

Swelling of the deeper nodes in the neck may displace the lateral pharyngeal wall and simulate peritonsillar abscess.

Acute lymphadenitis of the mediastinal nodes may be sufficiently severe to encroach upon adjacent structures and cause respiratory difficulty with dyspnea, stridor, cyanosis, difficulty in swallowing, and a harsh, brassy cough. Suppuration of these lymph nodes may lead to extensive mediastinitis. Mesenteric lymph nodes are commonly involved in acute gastrointestinal disturbances in infants and children and may cause abdominal pain, at times simulating appendicitis (p. 678), as well as vomiting and occasionally diarrhea.

**Course and Treatment.** When therapy with a sulfonamide or an antibiotic is instituted early, and proper attention is given to the primary site of infection, acute lymphadenitis of the superficial nodes usually subsides relatively rapidly. Either hot or cold applications may be used, depending upon which is more comfortable for the child. When suppuration with obvious abscess formation becomes apparent, aspiration by needle or incision and drainage is necessary.

#### CHRONIC LYMPHADENITIS

As a result of persistent or recurrent tuberculous or nontuberculous infection in any local area or in any system, the lymph nodes draining these sites may become chronically enlarged because of hyperplasia and chronic fibrosis. Such nodes are generally found in the cervical region as the result of chronic tonsillitis; in the cervical, axillary, epitrochlear and inguinal regions as the result of chronic eczema with secondary skin infections. Occasionally, chronic lymphadenitis of the mediastinal nodes results from recurrent bronchitis and bronchiectasis, and chronic mesenteric adenitis from infection in the gastrointestinal tract, not necessarily tuberculous. Protracted systemic infections such as syphilis, brucellosis or tularemia may produce chronic lymphadenopathy, which may be widely distributed. Neoplasms and metabolic diseases, such as Gaucher's disease and the related disturbances of lipid metabolism, may also produce chronic changes in the lymph nodes, which should be differentiated from chronic inflammatory processes. Biopsy is urgently needed if a diagnosis is in doubt after other appropriate diagnostic studies.

In conditions associated with chronic lymphadenitis the lymph nodes are only occasionally tender and are rarely painful. Local

treatment is usually not necessary. Treatment of the underlying condition is the most important factor. In subacute and chronic lymphadenitis of bacterial origin the systemic administration of an antibiotic agent must be prolonged for as much as two to three weeks. Resolution of the inflammatory process is slow, and relapses are common when antibiotic therapy is inadequate as to specificity, dose or duration.

#### NEOPLASMS OF LYMPH NODES

Primary neoplastic disturbances of lymph nodes appear to originate in their lymphoid or reticuloendothelial elements. Those which seem confined to a single cell type are classified as sarcomas: *lymphosarcoma*, if the predominant cell is a relatively mature large or small lymphocyte; *lymphoblastoma*, if a more primitive lymphocyte predominates; and *reticulum cell sarcoma*, when this cell is the one involved. Less readily differentiated morphologic types of cells are occasionally encountered, and the tumors have been given the names of *clasmatocytoma* or *monocytoma*. In other instances there is a multiplicity of abnormal cells, and no single cell seems to characterize the proliferative process. In *Hodgkin's disease*, for example, reticulum cells, eosinophils, granulocytes, multinucleated giant cells and abundant fibrous tissue occur in abnormal amounts and destroy the normal architecture of involved nodes. In *giant follicular lymphoma* a similar but less complicated picture is encountered: large follicle-like overgrowths of immature lymphoid tissue occur which compress normal tissue, destroy the reticular pattern of the node, and are associated with masses of abnormal multinucleated cells.

All these entities are sufficiently distinct clinically so that as accurate a diagnosis as possible should be made on a histologic basis to guide treatment and prognosis.

#### LYMPHOSARCOMA

Lymphosarcoma is a malignant neoplasia of lymphoid tissues. The similarities of lymphosarcoma and lymphatic leukemia, except for their sites of predilection, have become increasingly evident: leukemia involves bone marrow and produces striking alterations in the peripheral blood, whereas lymphosarcoma may be confined for varying periods of time to the lymph nodes. Patients with lymphosarcoma frequently have classic anatomic and clinical manifestations of acute lymphatic

leukemia in the late stages of their disease.

Lymphosarcoma may be found at any age; Berghinz observed it in the newborn infant of a mother suffering from the disease. In one series of 583 patients under fourteen years of age with malignant tumors, including leukemia, twenty-seven, or 5 per cent, were diagnosed as lymphosarcoma; the incidence is twice as high in boys as in girls.

**Pathology.** The normal architecture of the node is destroyed, and rarely there are areas of hemorrhage and necrosis. Microscopically, there is an overgrowth of large or small lymphocytes which infiltrate the fibrous tissue, invade the capsule and extend beyond its borders into neighboring tissues. Extension from lymph nodes into adjacent organs occurs late in the disease and may account for splenomegaly, hepatomegaly, pulmonary infiltrations and cardiac and renal involvement. Ultimately the bone marrow is involved in many patients, and it becomes impossible to establish whether the primary disease is lymphosarcoma or lymphatic leukemia.

**Clinical Manifestations.** The presenting symptom depends upon the site of involvement; it may be a visible mass when superficial nodes are primarily involved. Such masses are rarely painful, grow with varying degrees of rapidity, and are most frequent in the cervical, axillary and inguinal regions. The mediastinum is a relatively common site of lymphosarcoma, and cough may be the first complaint, followed by rapid development of tracheal or bronchial obstruction or by chylous pleural effusion. Occasionally, respiratory obstruction may constitute a medical emergency. Retroperitoneal lymphosarcoma may give rise to disturbed intestinal or urinary function, abdominal pain or abdominal enlargement due to chylous ascites. Involvement of the lymphoid nodules of the intestinal tract may cause intestinal obstruction.

As lymphosarcoma progresses there is widespread involvement of lymphoid tissue throughout the body, with symptoms indicative of interference with functions of the respiratory, gastrointestinal or urinary system. Fever, anorexia and cachexia become major clinical features; eventually, with involvement of the bone marrow, the picture is that of leukemia with hemorrhagic disturbances.

**Laboratory Findings.** Initially there are few if any distinctive laboratory findings. An acquired hemolytic anemia may occur early in lymphosarcoma, but is more common in adults than in children. The mechanism of

its production is not understood, but it may be related to the production of abnormal proteins by the neoplastic tissue (p. 954). These "antibodies" may create difficulty in cross matching blood. The bilirubin level is elevated when a hemolytic process occurs, and a reticulocytosis of some degree is found.

When lymphosarcoma enters the "leukemic phase," the peripheral blood and marrow will reveal findings typical of lymphatic leukemia. If renal involvement occurs, there may be profuse hematuria and even renal failure.

Roentgenographic examination of the chest will usually reveal extensive mediastinal shadows, and there may be pleural effusion. Enlarged retroperitoneal lymph nodes compressing the kidney may be responsible for distortion of pyelographic shadows. Osseous lesions similar to those of leukemia may occur.

The *diagnosis* is based upon the demonstration of characteristic histologic alterations in an involved lymph node. Inasmuch as characteristic changes are often not present, even in involved nodes, several nodes suspected of being involved should be obtained for study. A definitive diagnosis should not be made on the basis of equivocal evidence, and antineoplastic therapy should not be instituted until an unequivocal diagnosis is established.

Although careful evaluation of the peripheral blood will often indicate whether the bone marrow is involved, it will usually be worth while to examine an aspirated specimen of marrow to evaluate the degree of involvement and to estimate probable tolerance to potentially depressant therapy.

**Course and Prognosis.** Although a number of agents are temporarily helpful, no recoveries from lymphosarcoma are known. With optimal management, periods of well-being may be obtained for months or years.

**Treatment.** Results of surgical removal of isolated lymphomatous masses have been disappointing, but the potentialities may need re-evaluation in combination with newer modes of therapy, especially when the process seems confined to a single readily accessible area.

Roentgen ray therapy is perhaps the most effective treatment. Local therapy usually leads to almost immediate reduction in the size of the tumor masses, often with amelioration of fever, weight loss and other symptoms of hypermetabolism. Radiation should be used with great caution, however, for mediastinal

lesions when symptoms of respiratory obstruction are present, since the treatment may cause temporary enlargement of the mass and increased respiratory obstruction. In such cases treatment should be initiated with nitrogen mustard or related substances or with cortisone.

Nitrogen mustards exert a cytotoxic effect similar to that of roentgen rays. Owing to their cytotoxic effect, toxic symptoms in susceptible patients or in those given an excessive dose may be severe. Nausea and vomiting are commonly encountered, and diarrhea occasionally, but the most serious toxic effect is depression of bone marrow, with leukopenia, thrombocytopenia and anemia. Hemorrhagic manifestations may be especially severe and are accentuated by toxic damage to the endothelium of capillaries and small vessels. The depression of bone marrow is usually most manifest three to five weeks after administration of the drug. During this period the blood should be carefully observed for signs indicating need for blood transfusion or antibiotic therapy. Nitrogen mustard is contraindicated when there is extensive involvement of the bone marrow.

Nitrogen mustard is ordinarily given in a dose not to exceed 0.1 mg. per kilogram of body weight per day on four consecutive days. Bis-beta-chloroethylmethyl amine hydrochloride is commonly used. The course of therapy must not be repeated until after an interval of four to five weeks; toxic effects may not be manifest before that time. Nitrogen mustard is given intravenously and must be administered with great care, since injection into perivascular tissue leads to severe local necrosis. It is best given by injection into the tubing of an infusion set through which physiologic saline solution is being administered. The skin of the physician handling nitrogen mustard should be well protected against accidental contamination, and he should wear protective glasses.

An extensive search has been made among compounds related to nitrogen mustards for more effective substances. Of the many ethyleneimine derivatives which have been investigated, triethylene melamine (TEM) has proved useful. It has the advantage over nitrogen mustard that it can be given orally and rarely leads to as striking evidences of gastrointestinal toxicity. Unfortunately, more severe depression of bone marrow results from overdosage of TEM than from nitrogen mustard. The dose of TEM is not well established for

children; from 1 to 5 mg. is given each day for a few days, depending upon the age and size of the patient.

The antagonists of folic acid, the purine analog 6-mercaptopurine, and ethyleneimines other than TEM may also effect temporary control of lymphosarcoma. ACTH and cortisone sometimes produce dramatic reductions in the size of tumor masses.

As lymphosarcoma progresses, supportive measures should include blood transfusion for anemia or hemorrhage and antibiotic drugs for infections. Other measures, particularly those which support the emotional comfort of the patient and family, are similar to those suggested for the child with leukemia.

### HODGKIN'S DISEASE

Hodgkin's disease is a fatal disease in which there is chronic, progressive and painless enlargement of the lymph nodes and lymphoid structures in one or more regions of the body. It is relatively rare in infants, but becomes increasingly frequent after eight years of age. Males seem to be more frequently affected than females in childhood.

**Etiology.** The cause is unknown. A variety of infectious agents have been thought responsible, but none has been established. Evidences of malignancy, such as extension of the tumor beyond the boundaries of the lymph nodes and invasion of other tissues such as the bone marrow and liver, are common.

**Pathology.** The microscopic changes of early Hodgkin's disease are diffuse hyperplasia and proliferation of large reticuloendothelial cells. Some of the latter assume giant forms, both mononucleated and multinucleated; these are the so-called Dorothy Reed or Sternberg cells. An abundant admixture of lymphocytes and eosinophils is usually present; eosinophils may be particularly prominent. The normal architecture of the lymph node disappears, and is supplanted by irregular fibrosis, particularly late in the disease. Grossly, the lymph nodes may assume a semitranslucent, pinkish-gray appearance.

These changes may be altered materially by radiation therapy, after which the nodes become denser and harder and are matted together, owing to increased fibrosis.

**Clinical Manifestations.** The first evidence is usually painless swelling of one or more groups of superficial lymph nodes, often in the cervical region. Progressive involvement

of other nodes may follow, though the rate of extension varies considerably. Involved nodes tend to be discrete, elastic and usually fairly firm. Tenderness is rare. Mechanical pressure of the enlarging nodes may produce local manifestations, such as engorgement of the vessels of the neck, or edema. Involvement of mediastinal nodes is common and may account for such symptoms as cough, hoarseness, dyspnea and dysphagia. Involvement of abdominal nodes may produce ascites, and jaundice if the biliary tract is obstructed. The spleen is commonly enlarged and may become hard; it may extend as low as the umbilicus.

Occasionally the first manifestations are fatigue, anorexia and loss of weight, with a fluctuating fever, or they may develop as the disease progresses. Periods of high fever lasting one or two weeks followed by remission may occur at regular intervals (*Pel-Ebstein syndrome*). Loss of weight and wasting may occur in such instances. Pain from pressure of an enlarged node on nerve trunks, particularly along the vertebral column, may become severe and require constant sedation. An acute variety with sudden onset of fever, anorexia, nausea, vomiting, prostration, severe anemia, leukopenia and thrombopenia, but with little or no generalized lymphadenopathy, is occasionally seen. This type resembles lymphosarcoma and leukemia, both in its course and in the systemic infiltration, which develops rapidly.

**Laboratory Data.** The blood may show little or no change early in the disease, but as the bone marrow is invaded, a progressive hypoplastic anemia occurs. The number of leukocytes may vary from 5000 to 25,000 per cubic millimeter. Before aplastic anemia develops, the blood platelets are occasionally increased in number, and there may be an increase in number of monocytes. The neutrophils may show evidence of increasing immaturity. Frequently in the terminal phase in children there are thrombopenia, leukopenia (particularly lymphopenia) and severe anemia.

**Diagnosis.** As a rule the diagnosis can be made only by exclusion of other causes of chronic lymphadenopathy and by microscopic examination of a biopsied node. In the differential diagnosis, tuberculosis, chronic infection of the nose, throat and sinuses, primary or metastatic malignancies of the lymphoid tissue, leukemia and benign granulomatous processes such as cat-scratch disease must be considered.

**Course and Prognosis.** The duration may vary from a few months to several years. In the chronic type the patient may be in relatively good health for many months. Periods of remission may be so complete that the diagnosis seems doubtful. Recurrence is invariable, however, and death results from pressure on important structures, particularly in the respiratory tract with secondary infection in the lungs, or from cachexia and extensive involvement of bone marrow.

**Treatment.** When the diagnosis is established early in the disease, surgical removal of involved tissue may be justified, provided that complete extirpation of all enlarged nodes appears to be possible. Roentgen therapy is then usually administered over the involved region to the limit of the patient's tolerance. Roentgen therapy alone often produces remarkable results when the nodes are greatly enlarged and particularly when they cause pressure on the mediastinal or intra-abdominal structures. The enlarged nodes may shrink surprisingly rapidly, with complete relief from symptoms, but the effect is temporary. After a few weeks to several months the nodes enlarge once more, and another course of roentgen therapy may be less successful. Eventually the patient develops a tolerance to such treatment.

When roentgen therapy no longer provides symptomatic relief, or if the disease is widespread when first seen, treatment with nitrogen mustard or related ethyleneimine derivatives is preferred. Their use is identical to that described for lymphosarcoma (p. 994), and the same precautions must be observed. Triethylene melamine (TEM) and the thio derivative of triethylene phosphoramidate are also used; they are relatively easy to handle and produce few toxic symptoms. Relief of pain, decrease in temperature and a feeling of well-being are often evident within a few days. These agents do not appear to increase the period of survival beyond that expected from roentgenotherapy. Other supportive measures in Hodgkin's disease are similar to those of lymphosarcoma and leukemia.

# The Thymus Gland

The recognized clinical disturbances of the thymus gland are not many; they include infrequent instances of thymic tumors and abscesses, and the possible relationship of the thymic gland to myasthenia gravis. The thymus gland has occupied a uniquely important but incorrect place as a frequent cause of *respiratory obstruction* and of *sudden death*; in neither instance are there substantial data to justify a significant causative role.

**Anatomy.** The thymus is derived from the third and, at times, the fourth branchial pouch and normally descends to its position in the lower anterior part of the neck and upper part of the chest, where it resides just beneath the upper part of the sternum. Rarely the gland is entirely absent; somewhat more often there are failure of descent, unilateral or bilateral hypoplasia and fetal rests of thymic tissue in other organs, as, for example, in the thyroid and in the lungs.

The thymus has three distinct tissues: a medulla which contains the Hassall's corpuscles (transformed from the original epithelial cells), a cortex which is principally a lymphoid structure containing small round lymphocytic cells (*thymocytes*), and the supporting connective tissue. There are differences in the proportions of these various elements at different age periods. A decrease in parenchymal tissue begins about the time of puberty, with an increase in connective tissue and fat. The significance of the decrease in total size of the gland and especially in its parenchymal tissue with increasing age is not known.

For a number of years it was generally thought that a large thymus gland was a factor in respiratory obstruction and in sudden death. The data of Hammar and Boyd, however, indicate that the weights which had been considered to be those of normal glands were, in actuality, those of glands reduced in size by inanition and disease. Thymic tissue is extremely sensitive to the general nutritional status of the body. According to Boyd, severe undernutrition or disease (hyperthy-

roidism and leukemia are exceptions) will reduce the weight of the thymus by one third within three days. The range in weight of the normal thymus is indicated in Table 105. When the weights of the thymus in well nourished infants dying suddenly from adequately explained causes as automobile accidents are compared with those in well nourished infants dying suddenly from unexplained causes, there are no significant differences.

**Functions.** It is generally agreed that the thymus serves a lymphopoietic function, but there is no agreement on the many other functions which have at times been attributed to it. The principal controversy centers on whether or not the gland has any endocrine activity. The principal reported relationships are as follows: (1) Thymectomy results in genital hypoplasia, enlargement of the adrenal cortex, compensatory hypertrophy of the thyroid, and retardation of growth in the successive generation. (2) Castration, adrenalectomy or thyroidectomy prevents thymic involution or causes hyperplasia of the thymus. (3) Hypophysectomy in the prepuberal period delays involution of the thymus. The apparent relationship between the thymus and the adrenal has been responsible for an assumption that an adrenal factor rather than a thymic one may be responsible for the cases of sudden death attributed to status thymicolymphaticus. Park and McClure, after removing the gland from puppies, concluded that the organ served no essential need.

Thymectomy has been credited with improvement of some patients with myasthenia gravis. The postoperative studies of Harvey,

Lilienthal and Talbot indicate an increase in the amount of transmitter substance at the neuromuscular junction.

**Respiratory Obstruction.** Whether the thymus is ever responsible for significant respiratory obstruction is a controversial point. Although the thymus was once considered the most frequent cause of laryngeal and tracheal stridor, many clinicians of wide experience now think that it is never a factor. Laryngeal stridor and attacks of apnea and cyanosis can be explained otherwise in practically all instances if a careful study is made. The strongest arguments that thymic enlargement may be responsible for respiratory obstruction are bronchoscopic and roentgenographic observations of compression of the trachea. However, there may be some doubt whether the thymus was the cause of the compression, and in those instances credited to it some other factor may have been responsible.

There is no doubt that the thymus may cause a widening of the upper mediastinal shadow, which may be eliminated by shrinkage of the thymic tissue by roentgen therapy. There is no substantial evidence, however, that the size of this shadow bears any relation to respiratory obstruction or sudden death. Roentgenographic studies have also demonstrated that the size of the upper mediastinal shadow may be influenced by factors such as anomalous positions of the larger blood vessels, mediastinal lymph nodes, tumors, and pleural accumulations of fluid in the anterior-superior mediastinal area. Furthermore, the size and shape of the upper mediastinal shadow can be altered by a change from the horizontal to the upright position and by inspiration and expiration, the shadow being definitely larger during expiration. Roentgenographic studies for evidences of thymic enlargement should include a posteroanterior film taken in the upright position at the end of inspiration, as well as lateral films. No exact criteria are available for the range of normal measurements of the upper mediastinal shadow.

Whenever there are symptoms of laryngeal stridor, apnea or cyanosis, a complete examination with laryngoscopy, bronchoscopy and a roentgenologic study of the chest, including

visualization of the esophagus by means of barium, should be obtained (p. 877). In the majority of instances some condition such as a laryngeal or tracheal lesion, congenital heart lesion, vascular ring, chronic pneumonic infection, or tetany will be found to be the causative mechanism. Though one cannot say that there are *no* instances in which an enlarged thymus is the causative factor of respiratory obstruction, it must be extremely rare. The instances in which roentgen treatment is indicated are for practical purposes nonexistent. Routine roentgenographic examination of infants and small children for evidence of an enlarged thymus as a preliminary to a surgical procedure is now rarely practiced and is not indicated.

**Status Thymicolymphaticus (Lymphatism).** Lymphatism as a cause of sudden unexpected death is discussed on page 351. It may be stated here that the evidence available does not justify incrimination of the thymus as a cause of unexpected sudden and otherwise unexplained death. The term "status thymicolymphaticus" and its implication as a cause of thymic death should be abandoned because its use tends to inhibit an adequate search for the real cause of death.

**Neoplasms.** See page 1349.

# Disturbances of Cellular Lipid Metabolism and Related Conditions

## DISTURBANCES OF LIPID METABOLISM: THE LIPIDOSES

The term "lipid" is generic and includes all fats and substances compounded with fats. Disturbances of lipid metabolism are responsible for a number of clinical entities for which the term "lipidoses" has been proposed. Clinical interest is centered chiefly in xanthomatoses, xanthomatous tissue changes, Gaucher's disease, Niemann-Pick disease, Tay-Sachs disease, lipochondrodystrophy.

The common characteristic of these clinical disturbances is an accumulation of large, poorly staining, lipid-containing cells (histiocytes) which arise primarily from reticulo-endothelial cells in all parts of the body. Most of these diseases appear sufficiently different clinically, chemically and pathologically to be defined as clinical entities. However, occasional instances of organic involvement with cells containing poorly classifiable lipid material do occur. The specific lipid in most of the aforementioned diseases has been chemically identified and serves as one of the criteria for diagnosis and classification. Cholesterol and its esters accumulate in xanthomatous cells, cerebroside (kerasin) in Gaucher's disease and sphingomyelin in Niemann-Pick disease. In all instances a particular lipid predominates, but other lipids are also present abnormally in cells of patients with such disturbances.

Three mechanisms could be responsible for the lipidoses: (a) excessive production of a normal lipid and saturation of the tissues involved in its removal; (b) normal rate of production of an essentially normal lipid, but with an abnormality of the end organ tissues resulting in local accumulation (Unzmann's Gaucher lipoprotein hypothesis); (c) production of an abnormal lipid.

In Gaucher's and Niemann-Pick disease the lipid changes in the cells are well de-

veloped when clinical symptoms first become manifest. In the Hand-Schüller-Christian syndrome, on the other hand, the earliest lesion is a granuloma, and cholesterolization and xanthoma cell formation occur only with progression of the disease, if at all. Thus in this disease the intracellular lipid disturbance appears to be a secondary and not a primary manifestation, and for this reason the disease has been included in the reticuloendothelioses. Secondary xanthomatous tissue changes occur in other conditions when the reticular and histiocytic cells have an excessive amount of lipid material made available to them systemically as in hyperlipemic states, or locally as in chronic inflammatory reactions and neoplastic growths.

### GAUCHER'S DISEASE

Gaucher's disease may occur in two forms—the acute infantile type and the chronic type, which occurs in older children and adults. In both types the underlying disturbance is the accumulation of abnormal amounts of cerebroside in cells, primarily of the reticulo-endothelial system.

**Etiology.** The familial incidence is relatively high, but the simultaneous occurrence of infantile and chronic types is not seen within a single family. Gaucher cells may be found in the bone marrow of a parent or siblings of a patient in the absence of signs of the disease. The incidence is greater among Jewish people than in the general population.

**Acute Infantile Form.** The infant usually appears normal at birth, but soon exhibits apathy and progressive physical and developmental retardation. The abdomen becomes enlarged as first the spleen and then the liver increase in size. Subsequently neurologic

symptoms occur which progress and may include hypertonia and opisthotonos. Dysphagia and choking spells, severe cough and intermittent cyanosis are frequently present and are aggravated by increasing pulmonary infiltration with Gaucher cells. Cachexia becomes marked, and death usually occurs during the first year of life, the average duration of illness being six months after its recognition. The infantile form is rare as compared to the chronic form.

**Chronic Form.** The chronic form of Gaucher's disease is insidious in onset. More than 50 per cent of reported cases have their onset during the first decade of life. Neurologic symptoms are absent, and the disease is characterized by progressive enlargement of the spleen with resulting prominence of the abdomen. Anemia or joint pain secondary to bone involvement may also be initial symptoms. Hepatomegaly occurs early or late and is not as striking as the splenic enlargement. The patchy brownish pigmentation of the face, neck, hands and legs and pale yellow deposits in the conjunctivas described in adult cases are not ordinarily seen in pediatric patients. The disease may progress slowly or rapidly; anemia is usually prominent. Thrombocytopenia may result in hemorrhagic manifestations and often occurs early in the disease.

The bone changes, which are frequent, may give rise to pain and swelling in adjacent joints and produce a characteristic roentgenographic appearance consisting in flaring of the ends of the long bones (so-called Erlenmeyer flask appearance) with thinning and flaring of the cortex; these are most evident in the lower portion of the femur. In addition, widening of medullary cavities may occur in other bones such as the vertebrae, pelvis, tibiae and humeri, leading to pathologic fractures and severe deformities. The prognosis of the chronic form of Gaucher's disease is favorable as to life, but anemia and orthopedic problems may cause considerable handicap.

**Diagnosis.** A positive diagnosis may be established by demonstrating the characteristic Gaucher cell in the bone marrow. The enlargement of the spleen and liver and the bone changes are due to accumulations of these large, pale, round cells in the reticulo-endothelial system and diffusely in other cells as the disease progresses. The cytoplasm has a characteristic fibrillar appearance, and the nuclei are eccentrically located and frequently multiple. Gaucher cells are filled with kera-

sin, which was originally thought to differ from normal kersin in that it contains glucose rather than galactose. Why the acute infantile type of the disease has such striking neurologic involvement, which is absent in the chronic type, is unknown. Postmortem examination of the brain in the infantile type reveals a glial reaction and ganglion cell destruction with occasional foam cells.

**Treatment.** Splenectomy is indicated for symptomatic relief of pressure or thrombocytopenia, but no form of treatment has any curative effect upon the disease process. Transfusions may be indicated for anemia.

### NIEMANN-PICK DISEASE

This heredofamilial disease occurs predominantly in Jewish infants, and is usually fatal before the third year of life. The infant appears normal at birth, but soon begins to show physical and mental retardation. In spite of the general emaciation, the abdomen enlarges, and the spleen and liver usually become enormous. When the disease is fully developed, the infant appears apathetic and dull, the skin has a yellowish-brown appearance, especially on exposed parts, and anemia is usually present. The clinical picture is that of progressive emaciation and retardation (idiocy) with enlargement of the abdomen due to the massive size of the liver and spleen. Occasionally on fundal examination a cherry-red spot may be found identical to that of Tay-Sachs disease. Platelets are reduced in number late in the disease, in contrast to Gaucher's disease. Vacuolated cytoplasmic changes (lipid) in the monocytes and lymphocytes may be found in the peripheral blood. This finding is not present in other lipidoses, and thus is an important diagnostic feature.

Lipemia is not a constant feature of the disease, but rarely, and late, the fatty acids, cholesterol and lecithin, are increased in the blood. Sphingomyelin, which is increased in the tissues, is not increased in the blood. The Niemann-Pick cell with its waxy, highly refractile lipid droplets is usually readily identifiable in pathologic material obtained from bone marrow, splenic puncture or a biopsied lymph node. The cells stain characteristically with Smith-Dietrich stain (Fig. 307, A).

No treatment is successful, and death occurs in most cases before three years of age. Occasional cases are seen in which the course is relatively slow and mental deficiency may be minimal or absent.

A relationship between amaurotic idiocy

(Tay-Sachs type) and Niemann-Pick disease has been suggested, but at present they are regarded as separate clinical entities.

## XANTHOMAS OF THE SKIN

### (XANTHOMATOSIS)

The term "skin xanthoma" is applied to lesions which are yellow or orange, containing accumulations of fat, predominantly cholesterol. The inclusion of lipid diseases such as Gaucher's into a group called "xanthomatosis" is inappropriate.

Dermal xanthomas are classified on the basis of a normal or elevated serum cholesterol.

**Xanthomas with Normal Serum Cholesterol.** Xanthomas which exist in association

with a normal level of serum cholesterol either belong in the clinical category of xanthoma disseminatum (juvenile xanthoma) or are associated with one of the reticulo-endothelioses.

In *xanthoma disseminatum* the lesions are benign, appear in infancy, are usually multiple, are accompanied by no visceral involvement, and the patient grows normally. The cause of these lesions is unknown; they tend to disappear spontaneously, though slowly, and no treatment is necessary. The patient should be seen regularly and carefully checked with roentgenograms of the chest and long bones to rule out possible reticuloendotheliosis (Hand-Schüller-Christian disease, Letterer-Siwe disease, eosinophilic granuloma).

**Xanthomas with Elevated Serum Cholesterol.** Dermal xanthomas accompanied by elevated serum cholesterol are a part of the syndrome known as *xanthoma tuberosum* and are secondary to diseases which may produce chronic hyperlipemia. In *xanthoma tuberosum* the dermal lesions consist of soft yellow-brown nodules of variable size on the elbows, knees, buttocks and heels in contrast to the involvement of face and trunk in patients with *xanthoma disseminatum*. Xanthomatous swellings of the tendons may also be noted. The patient usually has relatives who have high serum cholesterol levels with or without skin xanthomas. The prognosis in this condition should be guarded, owing to the danger of involvement of the coronary arteries and

heart valves which may cause sudden death. Avoidance of excess dietary fat is recommended, but this yields no dramatic effect, since the body is able to manufacture cholesterol.

Finally, dermal xanthomas may be secondary to any chronic disease giving rise to high serum cholesterol levels such as diabetes mellitus, the nephrotic syndrome, idiopathic familial hyperlipemia, chronic obstructive hepatic disease, hypothyroidism and the hepatic form of glycogen storage disease. The prognosis for this type of dermal xanthomas is dependent entirely on that of the underlying disease.

SYDNEY S. GELLIS

## DISEASES OF THE RETICULOENDOTHELIAL SYSTEM: THE RETICULOENDOTHELIOSSES

This group of diseases includes the Hand-Schüller-Christian syndrome, Letterer-Siwe disease and eosinophilic granuloma. These syndromes are considered to be variants of the same underlying disease process, the etiology of which is unknown. The basic disorder consists in formation of granulomatous lesions of the reticuloendothelial system. Formerly the Hand-Schüller-Christian syndrome was included in the lipidoses because of accumulations of lipid in the form of cholesterol and cholesterol esters. Such accumulations may also be found in eosinophilic granuloma or Letterer-Siwe disease. Lipid deposits are most likely to occur in the slowly progressive forms of the disease and are considered secondary and not primary manifestations.

### HAND-SCHÜLLER-CHRISTIAN SYNDROME

Classically, but almost never observed, the Hand-Schüller-Christian syndrome consists in the triad of defects in membranous bones, exophthalmos and diabetes insipidus. More commonly the osseous lesions occur alone or in combination with other characteristic lesions such as *xanthoma disseminatum*, mild hepatomegaly, seborrhea of the scalp, pulmonary infiltrations and stomatitis.

The onset is insidious and usually occurs before the age of six years. Swelling and necrosis of the gums with sore mouth and re-

sorption of the alveolar bone with the extrusion of teeth (involvement of maxilla and mandible), aural discharge including involvement of the mastoid, and soft tissue swellings over osseous lesions may be the earliest signs of the disorder. Cutaneous manifestations are common and include papular rashes, seborrhea of the scalp, and petechial eruptions. Pinhead-sized nodules of *xanthoma disseminatum* may occur diffusely over the entire body or more often within the axillas and antecubital fossas or on the neck as isolated or grouped, yellow to mahogany colored, raised lesions. At this stage of the disease a roentgenogram of the skull usually discloses sharply defined defects or areas of bone rarefaction (Fig. 308). Other bones of the skeleton such as the long bones, pelvis, ribs and spine may be involved or may be the primary site of the disturbance. A biopsy taken during the early stage will show the histologic picture of a granuloma with a few scattered foam cells.

Later, growth and sexual development may be retarded, and diabetes insipidus may develop. Exophthalmos may result from accumulation of xanthomatous tissue in the retro-orbital region. Diffuse infiltration of the lungs with reticuloendothelial proliferation may result in extensive pulmonary fibrosis, and the roentgenographic appearance may superficially resemble that found in miliary tuberculosis or pneumoconiosis.

FIG. 308. Roentgenogram of skull of a child with Hand-Schüller-Christian syndrome, showing typical punched-out osteolytic lesions.

The lipid substances in the blood are not characteristically altered, and the total cholesterol is invariably within the normal range. There are no characteristic hematologic changes, although anemia is common in advanced stages of the disease. The osseous lesions, when not accompanied by other classic symptoms, may be confused with isolated bone cysts, osteitis fibrosa cystica, multiple myeloma, metastases of neuroblastoma, and osseous lesions of the lymphoma group. Diagnosis by sternal marrow aspiration is seldom successful.

The course is chronic, and spontaneous remissions may occur. The ultimate prognosis is uncertain and must be guarded even when patients are seen early and treated promptly. Intercurrent infection is not well tolerated.

The osseous lesions and the symptoms of diabetes insipidus are favorably influenced by roentgen therapy, but in many instances this effect is only temporary, and new lesions appear. Pituitrin substitution therapy by subcutaneous, nasal or rectal routes is effective in allaying the symptoms of diabetes insipidus.

### LETTERER-SIWE DISEASE

This is a disease of infancy and early childhood whose course is rapidly progressive and fatal. Apparently owing to the rapid course, xanthoma formation is minimal. The rapid progression accounts for the strikingly different clinical pattern from that of the Hand-Schüller-Christian syndrome, despite the similar basic pathologic process.

The clinical findings consist in moderate to extensive enlargement of the liver and spleen, generalized lymph node enlargement, anemia, leukopenia and thrombocytopenia with hemorrhagic manifestations, skin eruptions and skeletal changes, not unlike those seen in the Hand-Schüller-Christian syndrome. The infants fail to thrive and may have fever.

Eruptions of the skin usually appear early; they consist of petechiae, occasionally small macules and seborrhea of the trunk and scalp.

Biopsy of dermal lesions or lymph nodes permits the diagnosis of reticuloendotheliosis. In some areas foam cells containing cholest-

terol and cholesterol esters may be found in addition to the small reticuloendothelial cells. The recent procedure described by Moore of examining touch preparations from the skin for the presence of histiocytes is a valuable diagnostic aid.

The course of the disease has been affected little by radiation. At present corticosteroid therapy offers the only hope for these patients, and further experience with it is indicated.

### EOSINOPHILIC GRANULOMA

Eosinophilic granuloma is characterized by the presence of localized rarefactions involving one or more bones. Single lesions occur chiefly in older children and young adults; multiple lesions are common in younger children.

The onset is insidious, and the patient may be symptom-free, the lesion being detected on an incidental roentgenographic examination or because of the development of a spontaneous fracture. Symptoms, when present, usually are localized pain and tenderness with swelling of the adjacent soft tissues. Elevation of the white blood cell count occurs occasionally. Rarely a moderate eosinophilia may be present. Practically any bone may be involved, favorite sites being the cranial bones, the extremities and pelvis. On roentgenographic examination the lesion is clear cut and usually round or oval. The overlying cortex is not expanded, but may be destroyed by the process. Biopsy reveals a granulomatous inflammatory lesion containing mononuclear cells, polymorphonuclear leukocytes and varying numbers of eosinophils.

*Treatment* consists in surgical excision or roentgen therapy, either method resulting in rapid cure of the local lesion. The *prognosis* should be guarded, however, because of the

possibility of lesions elsewhere in the skeleton. The danger of lesions appearing later in the viscera or the skin must also be kept in mind, as well as the possible transition of the disease to the Hand-Schüller-Christian syndrome or to Letterer-Siwe disease. With increasing age the prognosis improves greatly.

# The Genitourinary System

## CLINICAL ASPECTS OF RENAL PHYSIOLOGY

The initial step in the formation of urine is the passage of all filtrable constituents of the plasma from the capillaries of the glomeruli into the capsular space. The amount of filtration or capsular fluid formed is influenced mainly by the hydrostatic pressure in the capillaries, which must be greater than the combined counterforces of the osmotic pressure of the plasma proteins and the intracapsular tissue pressure. The capsular fluid supposedly contains all filtrable constituents of the plasma in the same concentration except for variations in the ionic concentrations resulting from the absence of proteins in the filtrate (Donnan effect).

During the passage of the glomerular filtrate (ultrafiltrate of plasma) through the tubules certain "threshold" substances are, under usual conditions, completely reabsorbed in the proximal segment (glucose, amino acids), and others, such as creatinine, are not reabsorbed at all. The waste products which are not reabsorbed, irrespective of the plasma concentration, are called "nonthreshold" substances. It is thought that reabsorption of water, sodium, potassium, and the like, is accomplished by independent processes. The distal tubule regulates the acid-base balance of the body by selective reabsorption of bicarbonate and alkaline phosphate, ionic exchange with hydrogen ions and by synthesis of ammonia. The tubules also have an excretory capacity and clear such substances as Diodrast, para-aminohippuric acid, phenol red, penicillin and creatinine. Potassium can also be excreted by the tubules. Water is reabsorbed in the proximal segment and in the distal tubule, largely influenced by antidiuretic hormone.

Renal excretion of a substance may be accomplished by filtration, filtration with tubular reabsorption or filtration plus tubular excretion. If a substance is completely fil-

tered from the blood by the glomeruli and then completely reabsorbed by the tubules, the clearance of this substance will be zero (e.g., glucose). If a substance were to be completely filtered and not reabsorbed at all, then the clearance of this substance would be equal to the glomerular filtration rate (e.g., inulin). Obviously a substance being completely filtered and then partially reabsorbed (e.g., urea) would have a clearance value less than the rate of glomerular filtration. Other substances (para-aminohippuric acid and Diodrast) are excreted by the tubules as well as by glomerular filtration. The tubular clearance of these substances can be obtained by subtracting the amount filtered from the total quantity of the substance found in the urine. At low concentrations of para-aminohippurate or Diodrast in the plasma, the clearance of para-aminohippurate provides a measure of the quantity of plasma which perfuses the renal excretory tissues. However, since only 92 per cent of the para-aminohippurate in arterial blood is removed by one circulation through the kidney, it is better to speak of "effective" rather than absolute renal plasma flow. The renal blood flow is computed from the renal plasma flow and the hematocrit value. The ratio of the glomerular filtration rate to the renal plasma flow is known as the filtration fraction. In the kidney 20 per cent of the plasma perfusing renal excretory tissue is filtered by the glomeruli. Blood flow through the kidney is controlled by vascular resistance, largely the arteriolar glomerular bed, which is subject to chemical and nervous control. With emotional excitement and such conditions as shock and dehydration, which decrease blood volume, blood is diverted from the kidney by vasoconstriction. Vasodilatation, as, for example, during fever, results in a greater flow of blood through the kidneys. Denervation of

a kidney does not significantly disturb its blood flow, pointing up the autonomous control of its circulation.

### GLOMERULAR FILTRATION

The formula,  $UV/P$ , is used to express the plasma clearance for a particular substance;  $U$  is the concentration of the substance in milligrams in a milliliter of urine, and  $V$  is the rate of urine formation in milliliters per minute, so that  $U$  times  $V$  is the rate of excretion of a substance in milligrams per minute. If this value is divided by the plasma concentration of this substance ( $P$  equals milligrams of the substance per milliliter of plasma), then  $UV/P$  is the volume of plasma necessary to produce that quantity of substance excreted in the urine in one minute. The clearance of a substance is thus defined as the volume of plasma from which a substance is completely removed in one minute. In man, inulin, mannitol and many other substances which are completely filtered from plasma are used to measure the glomerular filtration rate.

In man the rate of glomerular filtration is relatively constant and independent of urine flow under ordinary circumstances. During deep sleep a significant fall in the filtration rate with no change in renal plasma flow has been noted. However, the decrease in urine volume at night is thought to be due to increased tubular reabsorption of water.

The glomerular filtration rate can be altered under certain circumstances. With extreme dehydration the rate tends to decrease, and with expansion of the extracellular fluid compartment it may increase. The average rate of filtration in man is 127 ml. per minute corrected to a standard surface area (1.73 square meters). About 85 per cent of the water is reabsorbed as a passive process in the proximal tubules and about 14 per cent through antidiuretic hormonal control in the distal tubules, leaving about 1 per cent for excretion as urine. It has been proposed that the function of the loop of Henle is to establish an isotonic urine prior to its entry into the distal tubule by means of passive diffusion of water through the thin loop. Hypertonicity of the urine is thought to be accomplished in the distal portion of the nephron.

The capacity of the normal person to form a concentrated urine is dependent upon the integrity of the hypophyseal system and upon the capacity of the tubular cells to respond

to the antidiuretic hormone. It is believed that the rate of hormone release under usual circumstances is approximately 0.1 to 0.3 milliunit per kilogram per hour. Adequate quantities of administered antidiuretic hormone will prevent or blunt water diuresis.

Administration of hypertonic solutions such as mannitol results in an increased urine flow with a urinary osmotic pressure approximating the osmotic pressure of the plasma (osmotic diuresis). Under these circumstances the distal water reabsorption may be limited to a maximal rate of 5 to 7 ml. per minute per 1.73 square meters.

The maintenance of a constant osmotic pressure is important to physiologic functions; the kidneys play a large part in maintaining this homeostasis. Excretion of sodium, a main cation of the circulating fluid, is controlled by such factors as glomerular filtration rate, plasma sodium concentration, actions of the adrenal cortical hormones, the natriuretic action of the antidiuretic hormone, the activity of the tubule cell and possibly by other influences. The amount of sodium excreted in the urine under normal circumstances is less than 0.5 per cent of that which is filtered. The reabsorption of sodium is supposed to occur in two active processes: first, proximal reabsorption, which is independent of passive water diffusion and accounts for about 80 per cent of the sodium filtered; second, distal reabsorption, which accounts for about 19 to 20 per cent of it. The maximal effect of mercurial diuretics is inhibition of sodium reabsorption in the distal tubules. A small fraction (about 1 per cent) may be involved in ionic exchange for hydrogen, ammonia or potassium.

Adrenal cortical hormonal control regulating excretion of sodium is demonstrated in patients with adrenal cortical insufficiency, in whom the output of sodium is greatly increased. This increase involves failure of tubular reabsorption, since it occurs in the face of a low glomerular filtration rate. The antidiuretic hormone, with certain reservations, can prevent tubular reabsorption of sodium. The effect of the antidiuretic hormone on reabsorption of chloride is more striking, since increased excretion of chloride is observed with small doses of Pitressin in which contamination with the oxytocic factor is not usually present.

Since reabsorption of chloride usually follows that of sodium, generalizations concerning reabsorption of sodium also apply to reabsorption of chloride. It is incorrect, how-

ever, to assume a similar mechanism for excretion of sodium and chloride under all circumstances.

Potassium, unlike sodium, chloride and bicarbonate, is excreted by the renal tubules as well as reabsorbed. The reabsorption of potassium is thought to occur in the proximal tubule, with excretion of it in the distal segment. Although the mechanism of potassium excretion is unknown, it is believed that it is exchanged for sodium. Adrenal steroids and antidiuretic hormones augment the excretion of potassium.

## TUBULAR REABSORPTION

The discussion so far has emphasized the specific role of the kidneys in regulating the electrolyte composition and fluid volume of the body. The following consideration will emphasize the role of the kidneys in the excretion of waste products or foreign substances, the conservation of other products and the maintenance of acid-base equilibrium.

**Diffusion.** Urea, the end product of protein metabolism, forms a large part of the urinary solutes (osmotic load). The plasma urea clearance represents the volume of plasma completely cleared of urea per minute. The urea clearance ranges from 30 to 60 per cent of the inulin clearance and is influenced by the urine flow. Urea is completely filtered by the glomerulus, but a large portion diffuses back through the tubular cells. Since urea excretion is influenced by many variables, it cannot be assumed that its clearance bears a direct relation to the filtration rate. However, the urea clearance is of value as a guide to appraise renal function.

**Active Reabsorption.** Substances which are not present in the urine or which appear in lower concentration than in the plasma cannot be reabsorbed by diffusion, but require the expenditure of energy. In such instances there is a limit on the quantity which can be reabsorbed in a given time (tubular maxima— $T_m$ ). Tubular maxima may be explained on the basis of the law of mass action, the transfer of a substance (glucose) from the tubular lumen through the cell being dependent upon a fixed quantity of cellular constituents which handle the transport substance (glucose), and the rate at which these constituents liberate the transfer substance to the blood. Another explanation may be the competition for available free energy. Since these systems are activated by enzymes, the possibility of the presence of enzyme inhibi-

tors which limit active transport of tubular substances must be considered. Several such transport systems have been described.

**Glucose.** Glucose is completely filtered from the plasma. The rate of tubular reabsorption of glucose is estimated by the difference between the quantities filtered and excreted per minute. As the plasma concentration of glucose is elevated, a level is reached at which the tubular reabsorption of glucose occurs at a maximal and constant rate. This maximal rate is designated by the symbol  $T_m$ , and a suffix is attached to indicate the substance ( $T_{mG}$ ). With further increases in the plasma glucose concentration no additional glucose can be reabsorbed; consequently glycosuria results. In man the average  $T_{mG}$  is 375 mg. per minute. Xylose appears to compete with the glucose transport system.

**Phosphate.** A large portion of the urinary phosphate is in inorganic form (acid and alkaline phosphate). Phosphate, the main buffer in urine, is utilized by the kidney in the excretion of acid and the conservation of base. Plasma inorganic phosphate is filtrable through the glomerulus and, since the urine may be free of phosphate, must be reabsorbed by the tubule. In dogs, when the plasma level is normal or below normal, all filtered phosphate is reabsorbed. Tubular reabsorption remains constant, so that when the plasma level exceeds this capacity, urinary spillage results.

Acidosis increases the excretion of phosphate, particularly during the first several days until the production of ammonia becomes significantly increased. Nevertheless the phosphate reabsorptive system is relatively stable and appears to maintain a constant plasma phosphate level.

**Amino acids.** Clearances are low. Extensive reabsorption of each amino acid must occur, and individual amino acids apparently are processed differently.

**Sulfate.** Sulfate is reabsorbed by an active process and is limited by a maximal rate of reabsorption. Sulfate reabsorption is independent of chloride and phosphate concentrations in the tubular urine.

**Uric acid.** Uric acid, an end product of purine base metabolism (nucleic acids), appears to have a maximal rate of reabsorption of about 15 mg. per minute. In man the uric acid clearance is about 6 per cent of the filtration rate.

**Vitamin C.** Vitamin C (not synthesized in man) is excreted when the plasma level is above 1.0 to 1.3 mg. per 100 ml. The rate

of reabsorption of vitamin C in man averages 2 mg. per minute.

## TUBULAR EXCRETION

A substance having a clearance greater than the glomerular filtration rate is either actively excreted by the renal tubules or synthesized by the kidneys. Many of these substances (para-aminohippurate, phenol red, Diodrast) are irreversibly bound to plasma protein albumin. The equilibrium between free and bound dye depends upon the amount of dye present and the protein concentration. The rate of excretion of a substance is limited by a maximal tubular rate characteristic for it. As the concentration of this substance is increased in the plasma, more will be excreted in the urine until the transport system reaches its limit. However, in tubular excretion, contrary to tubular reabsorption, all substances are apparently excreted by the same system. Competition occurs when two substances demanding excretion are present in the plasma.

**Creatinine.** Exogenous creatinine in man is excreted by the tubules. The ratio of creatinine to inulin clearance averages 1.4 to 1. Exogenous creatinine clearance is depressed by raising the plasma concentration of creatinine. Endogenous creatinine clearances are used as a measure of glomerular filtration rate; most methods measure endogenous chromogen materials. Since there are variations in the plasma endogenous chromogens throughout the day, serial plasma determinations are necessary. In renal disease the endogenous creatinine/inulin clearance ratio increases to as much as 2.6 to 1. The endogenous creatinine clearance may also vary from the inulin clearance under conditions of dehydration and with osmotic diuresis.

**Phenol Red (Phenolsulfonphthalein).** This dye is used to measure renal function because it is rapidly excreted under normal circumstances and its excretion is reduced in renal disease. This measurement is gross at best, however, when used in the customary way, because at low plasma concentrations the excretion of this dye approximates renal plasma flow and at high plasma concentrations measures tubular excretory capacity.

**Diodrast and Para-aminohippuric Acid.** At low plasma concentration para-aminohippurate and Diodrast are considered to measure renal plasma flow (about 640 ml. per minute). At high plasma concentration these substances are excreted by both the tubules

and the glomeruli. The maximal rate of excretion for Diodrast is about 53 mg. per minute, while that for para-aminohippurate is about 79 mg. per minute.

**Penicillin.** Penicillin is excreted by the tubules at a clearance rate of about 550 to 900 ml. per minute, a rate approximately equal to that of the renal plasma flow. A maximal rate for tubular excretion has not been found. Carinamide depresses tubular excretion of penicillin, resulting in a higher plasma concentration.

## SPECIAL CLEARANCES

**Sulfonamide Compounds.** The unconjugated sulfonamide compounds have clearances less than the glomerular filtration rate. These clearances are influenced by the rate of urine flow, the electrolyte excretion and the pH of the urine. The acetylated compounds are also excreted by the tubules, as evidenced by the fact that their clearance values are greater than the filtration rates. Clearances of the conjugated compounds are not constant, because these forms are bound to plasma albumin in variable amounts. Alkalinization of the urine diminishes the tubular reabsorption of certain sulfonamides. Sulfonamides are believed to inhibit enzyme systems of carbonic anhydrase and consequently to interfere with acidification of urine.

**Salicylic Acid.** The conjugated and unconjugated forms are excreted together. At low urinary pH the clearance is about 5; at higher urinary pH it may approach the glomerular filtration rate. Salicylic acid is conjugated with glycine to form salicyluric acid and possibly glucuronic acid. Plasma protein binding occurs with salicylic acid; conjugated forms appear to be excreted by the renal tubules. The unconjugated forms in an acid medium are reabsorbed by the tubules at a clearance ratio close to that of urea; in alkaline urine clearances tend to be increased.

## ACID-BASE REGULATION

Selective reabsorption of alkaline phosphate and bicarbonate by the tubules helps to restore the two main buffers to the plasma. Virtually all the plasma bicarbonate filtered through the glomeruli is reabsorbed at plasma bicarbonate levels of about 28 mEq. per liter or below; at higher plasma concentrations the excess is excreted in the urine. It is believed

that the proximal tubules reabsorb a large portion of the bicarbonate, and about one fifth of the total reabsorption occurs in the distal tubules. Since excretion of chloride depresses reabsorption of bicarbonate, an interdependent relationship is presumed between these two anions in the proximal tubules. The reabsorption of bicarbonate in the distal tubule is thought to be independent of water and chloride, being effected by the ion exchange mechanism. The mode of excretion and the mechanism of buffer action in the base-saving action of phosphate have been discussed earlier in this section. At a pH of 7.4 alkaline phosphate makes up about 80 per cent and acid phosphate about 20 per cent of the inorganic phosphate. At a pH of 4.8 nearly all the phosphate exists as acid phosphate, making available to the body almost one milliequivalent as base-saving equivalent per mol of phosphate excreted.

The tubular excretion of hydrogen ions results in replacement of base by an exchange mechanism. Bicarbonate is converted into carbonic acid, which eventually dissociates into carbon dioxide and water. The carbon dioxide remaining in the tubule passes into the blood and eventually is excreted by the lungs. The net result of this renal process is the saving of base. The average man excretes about 25 to 30 mEq. of free acid each day. The quantity of buffers within the tubular urine is a factor in determining the rate of excretion of titratable acid. During diabetic acidosis free acid excretion may reach values of 150 mEq. per day. In chronic glomerular nephritis, in which this mechanism of ion exchange is impaired, the excretion of titratable acid may fall to 2 mEq. per day.

The average excretion of ammonia in man is about 50 mEq. per day. This cation is excreted with fixed acids. With an excessive acid load as in diabetic acidosis, ammonia excretion may increase tenfold. Ammonia ions replace cations (sodium) and are excreted with phosphate and other fixed acids. The amide nitrogen of glutamine is believed to provide about 60 per cent of the ammonia excreted. The enzyme glutaminase, present in sufficient quantities in the kidney, is thought to catalyze the reaction of glutamine to ammonia. The remaining fraction (40 per cent) of ammonia excreted in the urine is believed to be derived from alpha amino nitrogen. Ammonia exchange is considered to occur in the lower portions of the nephron (lower distal segment).

## RENAL FUNCTION IN YOUNG INFANTS

Renal function in adults is used as a standard of reference in estimating renal functional capacity in the infant. Comparative body weight, height, surface area, renal weight and basal metabolic rate have been suggested as standards of reference. Most observers have used the adult surface area of 1.73 square meters as a reference, and, unless otherwise stated, the clearance values in this section are all corrected to 1.73 square meters. It might be more desirable to use one square meter as a unit, if only for simplification of calculations. Renal function in the young infant differs quantitatively rather than qualitatively from that in the adult. Adult values for glomerular filtration rate, renal plasma flow and maximal tubular excretion of para-aminohippurate may be reached in some infants by about six months of age and in most infants by two years. The glomerular filtration rate in the young infant is about 25 to 50 per cent of that of adult values. Factors contributing to the lowered filtration rate may include afferent arteriolar constriction, persistent fetal cuboidal glomerular membranes and small, underdeveloped glomerular capillaries.

Effective renal plasma flow, as measured by para-aminohippurate, averages about 20 to 40 per cent of adult values.\* Thus it would appear that more plasma (30 per cent) passes through the glomeruli of young infants than of adults (20 per cent). Clearance values for the maximal rate of tubular excretion (para-aminohippurate) are about 20 to 40 per cent of the adult values, indicating that glomerular function develops more rapidly than tubular excretory capacity at this age period. The maximal rate of tubular reabsorption for glucose is about 20 to 35 per cent of the adult range.

The young premature infant can concentrate urine to about half the capacity of the adult. Full maturity of this function can be attained as early as two months of age. The rate of solute excretion with osmotic diuresis is about half that in adults. This limitation of the infant's kidney must be considered when administering saline solution. With osmotic diuresis, water reabsorption in the distal tubule appears to be limited as in the adult, but this ceiling is not greater

\* Until extraction ratios for para-aminohippurate have been estimated in infants, these figures must be accepted as tentative values.

than 2 ml. a minute per 1.73 square meters (about one half of adult values). The response of the renal tubule of the young infant to intravenously administered Pitressin also appears to be less than that of the adult. Excretion of the major electrolytes is low in young premature infants, possibly 20 per cent of that in adults. Young infants excrete little inorganic phosphate, presumably owing to their lowered glomerular filtration rate. When additional phosphate is presented to the tubules of young infants, the proportion reabsorbed is less than that in adults. Since breast milk has a relatively low phosphate content, the excretion of phosphate by breast-fed infants is at a low level, resulting in less buffer substrate for base conservation.

The young infant seems to have no difficulty in diluting urine (water diuresis). As early as the fifteenth day of life he can excrete as dilute urine as the adult (as low as 50 milliosmols per liter).

With an acid load (chloride) premature infants excrete less urinary ammonia than do full term infants. However, some premature infants at thirty days of age studied in our laboratory were able to increase the urinary ammonia excretions by tenfold (136 mEq. per 1.73 square meters per day) in response to oral administration of 7 mEq. per kilogram of body weight per day of calcium

chloride. The young infant, per unit of surface area, can excrete hydrogen ions in response to an acid load comparable to the adult when sufficient phosphate buffer is made available in the tubular urine.

Bicarbonate excretion appears to follow the same pattern as it does in adults, and the mechanism for bicarbonate absorption and excretion may be fully developed early in life.

## URINE AND URINATION

The kidneys are distinctly lobulated and comparatively large at birth and generally extend below the crest of the ilium, especially on the right side. Their weight is about 23 gm. (0.8 ounce), or 0.75 per cent of the total body weight in contrast to 0.45 per cent in adult life.

The kidney is composed of a large number of individual units termed nephrons. The nephron consists of a capillary tuft or glomerulus and an unbranched tubule. There are about 1,000,000 nephrons in each kidney. The tubules drain into a series of collecting tubules, which in turn empty into the renal pelvis. In fetal and neonatal life Bowman's membrane is composed of cuboidal cells which later change into thin, flattened cells, and the glomerular tufts have fewer discrete loops. It is thought that these anatomic differences may account in part for the decreased

filtration rate (inulin, urea) of the very young infant.

In the kidney of the newborn infant, section often reveals reddish-yellow streaks in the apices of the papillae. These are deposits of urates (uric acid infarcts) chiefly in the straight portions of the tubules in the medulla. Sodium, calcium and phosphorus salts and oxalic acid may also be found.

The bladder of the infant is practically an abdominal organ, since the small pelvis is not capable of containing it.

## NORMAL URINE AND URINATION

Excretion in the human kidney begins about the ninth week of fetal life and is continuous. Dilute urine has been found in the bladder of the four-month fetus. At seven months' gestation uric acid has been found in the kidney, and urea has been detected in the

amniotic fluid as early as two and a half months of gestation.

**Amount.** Urine is usually present in the bladder at birth, but little is secreted during the first two or three days of life. Occasionally infants have considerable edema at birth, and much of this fluid may be excreted in the urine during the next forty-eight hours. As soon as the child begins to take fluid, the urinary secretion is increased and is proportionately greater throughout childhood than in adult life. The amount is exceedingly variable; it is influenced by many factors, such as the amount of liquid ingested, the environmental temperature and the states of the digestive and nervous systems.

**Frequency of Micturition.** The frequency varies from two to six times in the first and second days of life. Commonly the infant does not void until more than twelve hours after birth, and often not until the second or even the third day of life. Excretion after this is frequent during infancy, varying from five to thirty or forty times in twenty-four hours; the urine is often retained for several hours during sleep. After control of the bladder has been obtained, the frequency of urination varies from six to eight times in twenty-four hours.

**Physical and Chemical Characteristics of the Urine.** The specific gravity during the first few days of life is relatively high (1.012), but after the ingestion of milk begins it falls rapidly to 1.002 to 1.006. The infant's kidneys, however, are capable of concentrating during restriction of water. In the premature infant this concentrating capacity is limited. The full term infant attains the ability of the adult to concentrate urine by about three months of age. The loss of concentrating capacity is evidence of renal disturbance. When solid food is added to the diet, the specific gravity of the urine gradually increases.

The urine is at first highly colored and slightly turbid, owing to its concentration and to the presence of urates and mucus. Later, even during childhood, it is generally paler yellow than in adult life. Sometimes in infancy, particularly in the newborn, it stains the diaper faintly red through the decomposition of urates. The reaction of the initial urine of the newborn is decidedly acid, but after a few days approaches neutrality; that of the morning urine is less acid than that of the afternoon. The pH varies between 5 and 7. Odor is almost absent in freshly voided urine in infancy and even in childhood un-

less the urine is highly colored. The ammoniacal odor often noted in the nursery is due to delay in changing the diapers, the urine decomposing after it has been passed.

There is little *urea* in the urine at birth. The proportion is increased by the third day, but is still relatively low during infancy. Phosphates, chlorides and sulfates are present. The concentrations of these are increased when a mixed diet is started, but still are less than in adults. McCance showed that infants after the first few days of life reabsorb a greater percentage of their filtered sodium and chloride than do adults. The amount of urea is greater in childhood than in adult life, when compared on the basis of body weight, but forms a smaller percentage of the total nitrogen excreted than in adults. Approximately 80 per cent of the urinary nitrogen is excreted as urea, 5 to 15 per cent as ammonia, and the rest as uric acid, creatine and creatinine. (Approximately 2 per cent of the total urinary nitrogen is excreted as alpha amino nitrogen, and approximately 2 per cent of the milliequivalents of organic acids in the urine consists of amino acids.) The percentage of uric acid is especially high in the newborn period, after which it diminishes, but it remains higher in childhood than in adult life. The relation of uric acid to urea is 1:14 in the newborn and about 1:70 in the adult.

About 7 to 10 mg. of *creatinine* per kilogram of body weight are excreted daily by the newborn, about 20 mg. at two years of age, and 30 to 40 mg. in adult life. The quantity of creatinine excreted varies somewhat with the protein intake; nevertheless the daily output is relatively constant and is directly proportional to the amount of body musculature. Creatinuria has an important relation to thyroid activity, being low in the cretin and rising to normal levels with thyroid administration.

*Creatine* is excreted in variable and large

Table 106. Average Daily Excretion of Urine

Age	Fluidounces	Cubic Centimeters
First and second days.....	1-2	30-60
Third to tenth day.....	3-10	100-300
Tenth day to 2 months.....	9-15	250-450
2 months to 1 year.....	14-17	400-500
1-3 years.....	17-20	500-600
3-5 years.....	20-24	600-700
5-8 years.....	22-34	650-1000
8-14 years.....	27-47	800-1400

amounts by infants and to a less degree by children up to puberty; in the male excretion of it ceases a few years before this time. For some unexplained reason premature infants excrete almost no creatine.

*Indican* is not usually found in the urine of healthy breast-fed infants, but in those fed artificially indican is generally present in small quantity. Older children on mixed diets excrete indican to the same extent as do adults.

*Albumin* in small amounts may often be found in the urine of healthy newborn infants during the first ten days of life, and throughout childhood with very sensitive tests a small amount can usually be discovered (average, 35 mg. per twelve hours).

*Sugar*, detectable by ordinary clinical meth-

ods, is frequently found in the urine of the newborn and in early infancy, when relatively large amounts of sugar have been ingested. With tests more sensitive than the usual copper reduction one, carbohydrates, both fermentable and unfermentable, may be discovered in the urine of children (between 0.3 and 0.9 gm. per twenty-four hours).

*Glycocoll* is a normal constituent in the urine of the newborn, and *urobilinuria* is common in healthy infants. *Rennin* and *pepsin* (these being perhaps the same substance) are also discoverable in the urine of children.

Careful examination, as by the Addis count, will in normal children almost always reveal casts, red blood cells and white cells (see below).

## DIAGNOSTIC TESTS USED IN THE STUDY OF KIDNEYS

### TESTS MEASURING INFLAMMATORY AND ANATOMIC STATUS OF THE KIDNEYS

**Routine Urinalysis.** Special emphasis should be placed on tests for specific gravity, acid-base reaction, albumin, sugar, acetone and occult blood and on microscopic examination for white and red blood cells, epithelial cells, and casts.

**Addis Count.** This test, which determines the physical status of the nephron, is carried out as follows: A normal breakfast is served at 8 A.M. After this no fluids are permitted until the test is complete; the patient has a "dry" lunch and dinner. Before retiring at 8 P.M. the patient voids, and this specimen is discarded. All urine passed from this time, including a voiding at 8 A.M. the following morning, is combined as a single sample. In the normal child this twelve-hour collection of urine will contain up to 1,000,000 red blood cells, 1,000,000 white blood cells, 10,000 casts and 40 mg. of protein. This specimen also gives a good estimation of the concentrating power of the kidney. In the normal child, because of the limited intake of fluid, the specific gravity is usually over 1.022. In inflammatory renal disease there is a sharp rise in formed elements and in the quantity of albumin.

**Erythrocyte Sedimentation Rate.** This test is used to indicate the existence of inflammatory disease. Though it does not specifically indicate renal disease, it can be used to determine the continuation or cessation of known inflammatory renal disease.

**Intravenous and Retrograde Pyelograms** provide a means to detect gross anatomic abnormalities and a crude measure of renal excretory function.

### TESTS MEASURING FUNCTIONAL INTEGRITY OF THE NEPHRON

**Concentration Test.** This test measures the capacity of the kidney to excrete a concentrated urine,

which is largely a matter of distal tubular integrity. This is probably the most practical test of the functional status of the kidney; it may be used alone to follow the course of renal disease. As the disease progresses, the specific gravity falls and finally becomes fixed at low levels ( $>1.010$ ). When the specific gravity is fixed at a low level, large volumes of urine must be excreted in order to eliminate the waste products. When polyuria does not occur because of inadequate fluid intake, cardiac failure or renal inability to excrete water, the body wastes accumulate in the blood and tissue fluids, resulting in decompensated impairment of renal function. The inability of the kidney to concentrate in acute nephritis may be striking and persists long after the urea clearance test has returned to normal. If the diet is low in salt, the values may be falsely low.

When albuminuria is massive, the specific gravity should be corrected.

The concentration test can best be carried out as described under the Addis Count. Whenever there is

Table 107. Elevation of Specific Gravity of Urine\*

Quantities of Substances Needed to Elevate Specific Gravity of Urine 0.001 at 15° C.

Urea . . . . .	3.595 gm.

Sodium sulfate . . . . .	1.405 gm.
Albumin . . . . .	3.892 gm.

\* From Albarran, in Fishberg, A. M.: Hypertension and Nephritis. 4th ed. Philadelphia, Lea & Febiger.

a low specific gravity, it is important to observe whether edema fluid is being evacuated, since this may simulate the inability to concentrate.

The urine in early infancy is dilute. The specific gravity seldom rises above 1.010. The infant's kidney is capable of concentrating, however, and does so during dehydration. Infants of one to two months of age can concentrate urine solutes to a level of 1.2 osmols per liter. This is almost at adult level, which is about 1.4 osmols per liter. The premature infant rarely concentrates urine above 0.7 osmol per liter.

**Acid-Base Regulation.** The capacity of the kidney (distal renal tubule) to adjust its base-saving mechanisms (hydrogen ion exchange and ammonia production) in the presence of acidosis can be tested by administration of an acid salt such as calcium chloride. Under normal conditions, and in the presence of adequate phosphate excretion, the metabolic acids are excreted to some extent in free titratable form, and the pH of the urine falls. During this time some fixed base is lost in the urine. Within a day or so after birth there is a significant rise in ammonia production, and the metabolic acids are excreted in combination with ammonia to save body base. In the normal adult the ratio of ammonia/acid (titratable) varies from 1 to 2.5. The most acid urine which the kidney can form is pH 4.5. This capacity to excrete an acid urine and to produce adequate amounts of ammonia may be lost in the presence of disease. The premature infant is thought to have a limited capacity for ammonia production in response to an acid load.

#### TESTS MEASURING ABILITY OF THE KIDNEYS TO CLEAR BLOOD OF VARIOUS SUBSTANCES

**Urea Clearance.** Breakfast is withheld, but the child is given  $\frac{1}{2}$  pint of water to ensure an adequate urinary output. At the start of the test period the bladder is emptied and the urine discarded. After this, urine is collected for two to four hours. It is imperative that the length of the collection period and the quantity of urine excreted be measured with extreme accuracy, since the results of the test are based on the volume per minute of urine excreted. The length of the period is otherwise unimportant, except that longer intervals permit more accurate readings than shorter ones. A blood sample is obtained at a point midway in the urine collection. The blood and urine are analyzed for urea. The value of the urea clearance when the urine flow is 1.5 cc. per minute or over (maximum clearance  $UV/B$ )\* is constant and does not vary with the urine volume. Under such circumstances an average of 75 ml. of whole blood per minute is cleared of urea. When the urine volume falls below 1.5 ml. per minute, the clearance is said to vary with the square root of the urine volume—

standard clearance  $\frac{U\sqrt{V}}{B}$ . This equals an average

\*  $U$  = Micrograms of urea or urea nitrogen per 100 cc. of urine.

$B$  = Micrograms of urea or urea nitrogen per 100 ml. of blood.

$V$  = Volume of urine in cubic centimeters per minute.

clearance of urea from 54 ml. of whole blood per minute. In order to place the two formulas on a mathematically equivalent basis, the urea clearance, whether maximum or standard, is commonly expressed as per cent of normal. In children the urinary volume ( $V$ ) is corrected for the difference in surface area between the child and the adult. Urea clearance values above 75 per cent of normal usually, though not always, indicate intact renal function. Those between 50 and 75 per cent are in the doubtful range, and those below 50 per cent indicate decreased renal efficiency. In the presence of cardiac failure, however, low clearance rates should be accepted with caution.

Urea is filtered through the glomerulus and partially reabsorbed through the tubule, so that its total clearance is a measure of the functional status of both structures. In health approximately 60 per cent of the urea filtered finally appears in the urine. This is not a constant figure, however, for the slower the urine flows down the tubule, the greater is the amount of tubular reabsorption. Because of this variability the urea clearance test is not an accurate guide to the rate of glomerular filtration. The amount of urea that diffuses back into the blood is closely related to tubular reabsorption of water. This test should not be performed when the urine volume is rapidly increasing, for falsely high values may be obtained.

**Other Clearance Tests. Glomerular filtration.** This can now be estimated by measuring the clearance of the polysaccharide, inulin and the hexitols, mannitol, sorbitol and others. In the normal adult kidney  $UV/B$  for these substances averages 125 cc. per minute. The glomerular filtration rate in the infant in the first few months of life is at a much lower level. In the newborn period values from 40 to 50 cc. per minute are obtained (corrected to the adult surface area of 1.73 square meters). McCance and Widdowson recommend that the volume of total body water be used as the standard of comparison between infants and adults when measuring the glomerular filtration rate. These values gradually rise; many of them, when corrected for surface area, are within adult values by six to eight months of age, and most by two to three years. These sugars are not reabsorbed by the tubule and therefore are a measure of glomerular filtration.

**Tubular excretion.** Tubular clearance is measured satisfactorily by the excretion of Diodrast and sodium para-aminohippurate and somewhat less accurately by the excretion of phenolsulfonphthalein. At high blood plasma levels of these substances maximal tubular excretory capacity can be determined (see p. 1008).

**THE PHENOLSULFONPHTHALEIN TEST** is a less accurate but simpler test for the measurement of tubular function than the ones just mentioned. About 94 per cent of the injected dye is removed from the blood by tubular excretion. Clearance values around 400 cc. per minute have been described. A decrease in phenolsulfonphthalein clearance indicates either a decrease in effective renal blood flow (early in disease) or the presence of impotent tubules (late in disease), or both. The test is not sensitive enough to detect minor degrees of renal impairment. The dye is obtained in sterile ampules, 1 cc. of the solution

containing 6 mg. The test is most accurate when the dye is injected intravenously. About ten minutes before the injection the child drinks a glass of water and empties his bladder. In the so-called *fractional test* the urine, after the injection of the dye, is collected at fifteen, thirty, sixty and 120 minutes, the approximate normal amounts of dye excreted being, respectively, 35, 20, 10 and 5 per cent. Since the normal kidney can remove a large part of the dye in fifteen to twenty minutes, the usual two-hour collection periods permit the diseased kidney too great an opportunity to clear the blood of this dye. Catheterization may be necessary to obtain specimens on scheduled time in infants.

**GLUCOSE REABSORPTION TEST.** This test has been used to measure the tubular capacity to absorb solutes. Enough glucose must be given intravenously to raise the blood glucose to 600 mg. per 100 ml. in order to test tubular reabsorption under maximal capacity. The maximal reabsorptive capacity for glucose given by Goldring and Chasis for the adult is about 300 to 375 mg. per minute. In immature infants these values are considerably lower.

### RETENTION TESTS

In the presence of faulty glomerular clearance there is an accumulation of the substances in the blood normally cleared by the kidney. The more commonly estimated retentions are those related to some of the nitrogenous products: nonprotein nitrogen, urea nitrogen and urea. If the nitrogen balance and water balance are constant, the blood urea concentration (this also applies to the other nitrogenous waste products) varies inversely with the urea clearance. The normal figures for the three substances are as follows: urea nitrogen, 6 to 15 mg.; urea, 12 to 40 mg.; and nonprotein nitrogen, 25 to 35 mg. per 100 ml. of whole blood. The blood urea varies greatly with protein intake and dehydration, and in liver disease there may be a failure of deamination, producing a lowering of the urea concentration in the blood. Because the level of blood urea may vary independently of renal disease, it is hazardous to use it as a precise evaluation of glomerular disease.

Other substances may also be retained under similar circumstances. *Creatinine* in severe renal failure may rise from a normal level of 2 mg. per 100 ml.

of blood to 10 mg. or more. *Uric acid* may also rise from a normal level of 2.5 to 3.5 mg. per 100 ml. of blood. It may rise before the blood urea rises. *Phosphate, sulfate* and *potassium* may also be retained in renal insufficiency. Various organic acids are also retained when renal insufficiency is advanced.

### BLOOD PRESSURE

Since many symptoms of renal disease depend on vasospasm brought about by the primary renal disease, estimation of the degree of vasospasm as reflected in the blood pressure is an important guide in following the course of the disease.

## DISORDERS OF URINARY SECRETION

### DISTURBANCES IN QUANTITY OR EXCRETION OF URINE

Decreased urinary output may result from decreased formation of urine or retention of it in the bladder.

#### OLIGURIA

Urine may be secreted in small amount (*oliguria*) or, temporarily, not at all (*anuria*). This situation may be normal in the first

twenty-four hours of life. Pathologic causes in the newborn infant include renal agenesis, anomalies such as polycystic formations and obstructions resulting in hydronephrosis, acquired lesions such as thrombosis of the renal vein and renal artery and renal infarction and, most often, dehydration with anhydremia of any cause. After the newborn period any of these factors may be causative,

anhydremia, as in diarrheal disease, being the most frequent one. Suppression of urine is characteristic of acute glomerulonephritis, in poisonings by various metals and drugs and in conditions productive of shock and so-called lower nephron nephrosis. Obstruction of the renal tubules by crystallization of sulfonamide drugs is an example of mechanical blockage.

## RETENTION OF URINE

Formation of urine is not necessarily impaired, but there is failure of the bladder to expel it. In the newborn this may be due to malformation of the urinary tract, such as marked phimosi or atresia of the labia, or to urethral obstruction by abnormal folds of mucous membrane, uric acid crystals or a calculus. A balanoposthitis, vulvovaginitis, or inflammation of the meatus may cause retention, owing to the pain (*dysuria*) which urination produces. Disturbances in the innervation of the bladder and various reflex or direct inhibitions are factors, as in myelomeningocele, meningitis, myelitis, rectal irritation, spasm of the vesical sphincter, hysteria, mental depression, and the debility associated with severe febrile diseases.

## POLYURIA

Polyuria is a large increase in the amount of urine. It occurs in a variety of conditions and situations, including diabetes mellitus, diabetes insipidus, chronic renal disease and the recovery phase of so-called lower nephron nephrosis. It is also observed when a large amount of fluid is imbibed and during the reduction of edema. Nervous excitement and chilling of the body surface may produce a temporary increase in urinary secretion.

## FREQUENT URINATION

(POLLAKIURIA)

This is normal in the first two years of life. It also occurs with polyuria, cystitis and nervous excitement and from reflex stimulation by renal calculi. A highly concentrated acid urine causes it by irritation of the bladder.

## INCONTINENCE OF URINE

Incontinence depends upon a variety of causes. It is observed with phimosi, cystitis, impaction of a calculus in the urethra, para-

lytic conditions of the bladder resulting from disease of the brain or spinal cord, including spina bifida, and in profound exhaustion or coma. The bladder becomes overdistended until there is persistent overflow, or sometimes an intermittent expulsion of urine without the patient's knowledge. Malformations such as exstrophy of the bladder, abnormal openings of the ureters into the vagina, persistent urachus and absence of the vesical sphincter allow the urine to flow constantly. With partial obstruction, as from a malformation in the posterior urethra, the overdistended bladder often produces a constant dribble of urine. Incontinence is a characteristic symptom in many idiots, being then a form of enuresis.

MITCHELL I. RUBIN

## ENURESIS

Enuresis is defined as involuntary discharge of urine, but is generally used to indicate bed-wetting (nocturnal enuresis) by children beyond the age when control of the urinary bladder should have been acquired. There is considerable variability in the age when children acquire voluntary control of urination. A few achieve it between nine months and one year of age. The majority do not begin to have voluntary control before fifteen to eighteen months of age, and it is usually between the ages of two and three years when nocturnal control is firmly established. Some, usually boys, may not be dry at night before four to six years of age. Neuromuscular control sufficient for walking indicates that the child is physiologically ready to inhibit the normal emptying reflex of the bladder. This control is a willed effort and is dependent upon other factors than neuromuscular maturation. Even in children who have acquired good control there may be, for several years, occasional lapses associated with fatigue or emotional turmoil. The child with enuresis may occasionally have an "accident" during the day because of excitement, extreme urgency or engrossment in play. When there is continual involuntary discharge of urine, however, it is likely that the child has some organic disturbance.

Enuresis is a common symptom; estimates of its incidence vary from 5 to 15 per cent of all children, about twice as many boys as girls being affected. Blomfield and Douglas, in a recent survey in England of a random sample of 4294 children, found that 12.2

per cent wet the bed at four years of age and 7.3 per cent at eight years of age. The rate was highest in the lower socio-economic group. In the older age group, particularly in the upper economic level, boys outnumbered girls. Enuresis is associated with all degrees of intellectual capacity and occurs in all strata of society.

**Etiology.** The cause is usually an emotional disturbance in the child, secondary to a disturbed parent-child relationship. Infrequently, enuresis may be a symptom of nocturnal epilepsy or of lesions of the lower spinal cord or the genitourinary system. It may be an early symptom of diabetes mellitus or diabetes insipidus. Campbell doubts the assumption that organic lesions are rare as the cause of enuresis. He feels that about 10 per cent of such children have some pathology of the genitourinary tract and stresses the need for thorough re-examination of children whose enuresis has been assumed to be on a psychogenic basis, when they are not cured within two or three months.

The most common cause of persistent bed-wetting from infancy is too vigorous attempts at toilet training, before the age of physiologic readiness (usually fifteen to eighteen months). This produces confusion in the child. If the infant cannot do what he is asked to do, he becomes frustrated and guilty or antagonistic toward his parents. All too often this antagonism influences other patterns of behavior, and the effects upon the developing personality of the child are of much greater consequence than achieving early urinary control. When there is a healthy, warm parent-child relationship, it may be doubted whether the absence of efforts to train the child will result in continued wetting; many a mother reports that "her child trained himself."

Enuresis which develops after control has been established is usually associated with a temporary lack of security within the child. The birth of a new sibling, moving to a new home, separation from parents by illness or entering school may precipitate enuresis. Tonsillectomy, circumcision and other operative procedures may also be followed by periods of enuresis. Rigorous efforts to eradicate thumb- and finger-sucking or masturbation may also bring it on. When such factors do cause enuresis, it is usually an indication that the child's ability to adjust is not well developed and that the relationship between child and parents needs strengthening. Frequently measures designed to foster the child's

sense of security in the family group are sufficient.

There is often a history of enuresis in parents, grandparents or other relatives. This is said by some to indicate a hereditary trait. Although one cannot rule out some hereditary predisposition, it seems more likely that unsatisfactory adjustment transmitted by parents who have not succeeded in working out their own emotional equilibrium is the precipitating cause.

Some children without evident lesions void small amounts of urine at frequent intervals with considerable urgency. Such children are said to have an "irritable bladder"; belladonna is helpful in some of these children, but not in all. Bed-wetting frequently causes concern when the child is about three years of age and is passing from the light sleep of infancy to the heavy sleep of childhood. If the habit of urinary control is not established before this time, it will inevitably be more difficult to establish. It seems doubtful, however, whether the depth of sleep plays more than a secondary role in the causation of enuresis.

At one time spina bifida occulta was thought to be a common cause of enuresis. Karlin has shown that this is so only in children with gross defects of the spinal cord. A variety of physical conditions, such as phimosis, adherent clitoris and infected tonsils, have been suggested as the cause of enuresis. Though treatment directed against these conditions often has been associated with cessation of enuresis, a causal relationship is not necessarily established. Treatment which is dramatic or painful, as, for example, by instrumentation or injection, may stop bed-wetting, but it does not get at the underlying emotional factors and may actually increase them.

**Clinical Manifestations.** From the mild cases in which the bed is wet only occasionally there are all grades of severity up to those in which the bed is wet one or more times each night. Sometimes children dream that they are passing urine and may be awakened by the accident, but as a rule they are not aroused by the involuntary micturition. Bed-wetting may occur at any hour of the night, but frequently it occurs before midnight and may occur in spite of drastic restriction of the child's fluid intake.

Diurnal enuresis at times develops after nocturnal enuresis has continued for some time. The child has a frequent urgent desire to evacuate the bladder, which may come on so suddenly that the clothing is wet before

he can reach the toilet. In severe cases the patient is constantly wet with offensive, decomposing urine; in such instances some organic cause or a severe emotional disturbance is likely to be present. In some children play, exercise, sudden laughing, fright or other emotion is followed immediately by evacuation of the bladder.

**Diagnosis.** The diagnosis is made on the basis of a history of persistent bed-wetting with or without occasional "accidents" during the day hours and in the absence of evidence of neurologic or genitourinary disease, nocturnal epilepsy, diabetes mellitus or diabetes insipidus. When incontinence of urine is due to malformations or paralysis of the bladder, there is constant dribbling. In enuresis of the type discussed here the urine is always passed in a stream.

Every child with enuresis should have a careful physical examination and urinalysis, and he should be observed to see whether urine is passed in a stream; special studies should be limited to those clearly indicated by the history and physical examination. Indiscriminate instrumentation may cause the enuresis to disappear, only to have the child manifest other evidence of his disturbed feelings. Careful inquiry usually reveals evidence of other emotional disturbance, such as eating difficulties, overdependence on parents, thumb-sucking, nail-biting and other signs of immaturity. Despert found that enuretic children have difficulty in giving outward expression to their aggressive impulses.

*The diagnosis of an emotional disturbance in a child is not made by first excluding physical disease; the two conditions are not mutually exclusive. Difficulties in the emotional area are diagnosed by history, observation of the child's behavior and an evaluation of the parent-child relationship.*

**Prognosis.** The prognosis is determined by the underlying causes and the ability to cope with them. Most children stop wetting the bed before or during puberty. Enuresis, however, indicates that the child is having difficulties in growing up. The pressures which may have been used to force the child to acquire urinary control may have and may continue to have pronounced effects on his personality structure and adjustment. They frequently set the stage for the child to have continued difficulty in relating to authority. This may be the authority of learning in school or of the rules of society. Frequently the guilt of his own behavior interferes with the confidence and effectiveness of his ap-

proach to life. Enuresis sets him apart from others, exaggerates his feeling of difference and may make him uncertain of himself. Prognosis should be measured in terms of the child's total adjustment and not merely in terms of his ability to control urination.

**Prevention.** If parents could be guided in the institution of bladder training at appropriate times, if the element of struggle could be eliminated from the training process and from other areas of the parent-child relationship, enuresis would not be a significant problem. If parents, particularly mothers, could uniformly have the opportunity of friendly and informed consideration of their problems in child rearing by a competent physician, many factors which insidiously distort the parent-child relationship would be eliminated. In other words, if parents can be helped to be intelligently aware of and emotionally responsive to their child's needs, enuresis and many other manifestations of disturbed emotional growth would rarely appear.

**Treatment.** In children who have persistent enuresis, treatment is often slow and difficult. Attitudes developed during early training and the succeeding years affect the parent-child relationship so that it is difficult to modify it. The initial open struggle often has subsided, leaving partially concealed irritations and disgust in the parent and a discouraged, antagonistic attitude in the child. The effect of such feelings on the happiness and general adjustment of the child is apparent. The emotional growth of children has little chance of being healthy if the relationships with parents are not warm and unencumbered by chronic open or hidden antagonistic or critical feelings.

An approach which aims at helping the parents in understanding and improving their relationship with the child and at the same time offers to the child some aid to complement his own efforts is most likely to succeed. The parents should understand that scolding, punishing and shaming only make it more difficult for the child to control urination, and that encouragement, patience and acceptance build up his self-confidence and his desire to be dry.

There is a variety of approaches to the control of the bed-wetting itself. Their principal purpose is to give the child the feeling that he has support in his efforts to control his bed-wetting. Limitations of fluids, getting the child up one or more times during the night and various medical preparations may

be useful. Recently an old method has been revived and is being commercially exploited. It is a conditioning type of treatment with a pad in which urine completes a circuit which sets off a bell. A basically similar method was described by Pfaundler in 1904. Such conditioning methods may occasionally have their place if one is first sure that the parent-child relationships are not seriously awry and the child not seriously disturbed. Their indiscriminate use is contraindicated.

There are differences of opinion about the benefit derived from restriction of fluids in the latter part of the day. At least an excessive intake should be avoided. Such moderate restriction as a half-glass of milk at the evening meal and no fluids thereafter until morning, except during extremely hot weather, may be recommended.

The child should empty the bladder just before going to bed. In the child three to five years of age all that may be required for the control of enuresis is to take him from bed, awaken him and place him on the toilet three or four hours after his retirement. Some clinicians have advised a similar plan for older children, except that the child is responsible for his own awakening and for going to the toilet. An alarm clock is set for an arbitrary hour, as, for example, 1 A.M.; if the bed is not wet at this time, the period before awakening is gradually prolonged.

Tincture of belladonna is a useful adjunct; it has some effect in relaxing a hypertonic bladder and allowing it temporarily to retain more urine. The child should be encouraged to believe that it will help, but that it will not completely replace his own efforts to stay

dry. It may be started at a dose of 5 drops three times a day and increased a drop per dose per day until there are signs of atropism; a maintenance dosage just below this level is then desirable until it is apparent that the enuresis is not being controlled or, if it is controlled, for an additional two or three weeks. During this period the dose may be tapered off.

Many physicians have found that a direct relationship through frequent visits by the child without a parent is helpful. There need be little discussion beyond a brief report from the child and an occasional simple suggestion by the physician. There should be an attitude of both working together to solve a common problem.

Unfortunately there is a significant number of children with enuresis whose relationships with their parents are complicated by severely disturbed feelings. Efforts at straightening out such situations are often unsuccessful without direct psychiatric treatment of the child and help to the parents. Such treatment can best be accomplished in a child guidance clinic or by a child psychiatrist. Recognition of such cases depends upon experience in evaluating the degree of the disturbance. If psychiatric treatment is not available, an attempt at understanding and modifying the situation is worth while by the pediatrician or family physician.

## ALTERATIONS IN COMPOSITION OF URINE

For Alcaptonuria and Cystinuria, see pages 259 and 262.

### ALBUMINURIA

#### PHYSIOLOGIC OR BENIGN ALBUMINURIA

Delicate tests show albumin in the urine of most persons; the average normal excretion in twelve hours is between 30 and 50 mg. More marked albuminuria may occur transiently during the newborn period. Small amounts of albumin may be found after violent exercise, overeating and cold bathing. Albuminuria is not infrequent during acute

infections, states of dehydration, and in diarrheal diseases and cardiac failure. These forms of albuminuria depend primarily on the extrarenal disturbance.

#### ORTHOSTATIC ALBUMINURIA

(POSTURAL, CYCLIC, LORDOTIC ALBUMINURIA)

In this entity, albumin, which is derived from the serum proteins, appears in the urine after the child has been standing or sitting and disappears when he lies down.

**Etiology.** The mechanism of this disturb-

ance is not clear. In some instances anatomic renal defects seem to be a factor. One theory ascribes the albuminuria to a diminished pulse pressure. The most widely accepted view is that in the erect position the child develops an exaggerated lumbar lordosis which by pressure interferes with renal circulation, resulting in a rise in renal venous pressure. Compression of the inferior vena cava is also thought to be a factor. Faulty posture, however, is not present in many of these patients; conversely, not all children with lumbar lordosis exhibit albuminuria. Evidences of vasomotor instability in some of these patients suggest that alterations in vascular control of the kidney may also be responsible. Orthostatic albuminuria occurs most often in late childhood, with equal frequency in males and females; a familial tendency has been noted.

**Clinical Manifestations.** The quantity of protein in the urine varies from a trace to 8 to 10 gm. a day. The protein is composed chiefly of albumin, although occasionally large amounts of globulin are found. A substance considered to be a mucoprotein (precipitated by acetic acid in the cold) is often found in small amounts. In some instances a posture which will increase the lordosis will increase the amount of proteinuria. Casts are rarely found, but when present, they disappear when the child is lying down. In rare instances children with orthostatic albuminuria have greatly diminished but persistent albuminuria when lying down. In such instances nephritis must be differentiated.

The patient's general health may be good, or more often there may be faulty nutrition, anemia, fatigability, headaches or various nervous symptoms. Digestive complaints and constipation are common, but are probably not related to the albuminuria. The patient is often lordotic and slender, and tends to be tall and asthenic. There may be intermissions when the albuminuria disappears for weeks or months. There is no evidence that the protein stores of the body are depleted. The disorder, which is benign, tends to disappear after adolescence, but may persist into adult life.

**Differential Diagnosis.** Orthostatic albuminuria should be carefully differentiated from nephritis. The persistence of albuminuria in the night specimens and the presence of red blood cells and casts in the routine urinalysis are evidences in favor of nephritis,

as is a demonstrated decrease in renal function. Occasionally in chronic nephritis albuminuria may increase while the patient is in the upright position.

**Treatment.** Treatment consists in improvement of the general health. Protein should not be restricted, but should be given in amounts adequate to take care of the regular needs and to replace that lost in the urine. Attention should be paid to improvement of muscle tone and correction of any faulty posture. The child should be allowed a normally active life, since there is no evidence that restricted activity will speed the disappearance of the condition.

#### *FEBRILE ALBUMINURIA*

Albuminuria occurs commonly in association with high continued fever from any cause, but disappears on cessation of the fever. The urine is highly colored and concentrated, and contains a small amount of albumin and occasionally a few hyaline or epithelial casts.

#### *ADVENTITIOUS ALBUMINURIA*

The presence in the urine of blood or purulent material in sufficient quantity will produce an albuminuria. Bence-Jones type of protein is found in the urine of patients with multiple myeloma.

#### *GLYCOSURIA*

Glucose is usually present in the urine of normal persons in amounts not detectable by commonly used tests (p. 1012). The presence of readily detectable glycosuria indicates either a high level of blood glucose (hyperglycemia) or faulty tubular reabsorption of glucose. Hyperglycemia may result from excessive ingestion or parenteral administration of sugar or from some metabolic disease such as diabetes mellitus. Deficient tubular reabsorption may result from a congenital defect (renal glycosuria and such entities as the de Toni-Fanconi syndrome and cystinosis and other defects of renal tubular function associated with amino-aciduria and phosphaturia), from cellular infiltration (glycogen disease), from cellular damage (mercury, lead or opium poisoning) or from altered tubular cell function (phlorhizin and disturbances in the hypothalamic area of the brain). Feeding large amounts of saccharose to normal infants may produce saccharosuria, sometimes with elimination of glucose and

levulose as well. The term *alimentary glycosuria* is used when glucose is excreted by healthy children after excessive ingestion of it. Transient glycosuria may also result from emotional disturbances, excessive physical activity, febrile diseases, convulsions, meningitis, brain tumors or brain injury, and in hyperthyroidism.

*Renal glycosuria* is the term used for a genetic defect in the reabsorption of glucose by the renal tubules which results in an abnormally low renal threshold for glucose. The fasting blood sugar level is within the usual range or below it, and the glucose tolerance curve is normal or low. The glycosuria per se is not handicapping, except that affected children may suffer ketosis more readily than normal ones, especially during febrile episodes, with vomiting or when the dietary intake is low. It must, of course, be differentiated from diabetes mellitus.

### PENTOSURIA

Pentose will reduce copper slowly, but is not fermentable. It is said to occur sometimes after ingestion of fruits such as pears, plums, cherries and strawberries. In most instances pentosuria is a rare, benign, congenital metabolic disorder, most common in Jewish males (see p. 277).

### GALACTOSURIA

Galactosuria may occur in normal infants after ingestion of large amounts of lactose and in those with chronic galactosemia, a congenital metabolic defect (p. 274).

### LITHURIA

Some uric acid is always excreted in the urine, even during complete starvation. The amount is increased during states of indigestion; in increased destruction of tissue, as in leukemia, anemia, lead poisoning, pneumonia; and by increased ingestion of purine bases. In the urine of the newborn infant it may be precipitated and form a whitish or reddish deposit upon the diaper. Uric acid may be precipitated in the bladder when the urine is highly acid, and give rise to pain on micturition. In the newborn infant there may be uric acid infarctions of the kidney, producing attacks of abdominal pain, which otherwise are without importance. When treat-

ment is deemed necessary, water should be given freely and the urine alkalinized.

### INDICANURIA

Indican is usually present in small amounts in the urine of artificially fed infants. It is increased in digestive disturbances, being frequently associated with constipation.

### LIPURIA

Fat in the urine may depend upon an excess of it in the food or upon fatty degeneration of the kidneys. Fat in the urine is found frequently in small amounts during uncontrolled diabetes mellitus, in nephrosis and in the nephrotic stage of chronic nephritis.

In *chyluria* there is sufficient fat to give the urine a milky appearance, and there may be albuminuria and red blood cells as well. Chyluria results from blockage of the lymphatic system, with leakage of chyle into the urinary system; some cases are due to filaria.

### ACETONURIA

The ketone bodies (acetone, aceto-acetic acid and beta-oxybutyric acid) may occur in small amounts in the urine of healthy infants and small children. An excess indicates inadequate carbohydrate metabolism, but not necessarily an acidosis. The ketones are normal metabolic products of fat combustion within the liver and are oxidized by the muscles. Only when ketones are produced at a rate which exceeds the capacity of the muscles to oxidize them are they excreted in the urine. Acetonuria occurs much more readily in young children, except in early infancy, than in older ones and adults and is a common finding in association with persistent vomiting, starvation, acute digestive diseases and acute febrile disorders, as well as with diabetes mellitus.

### HEMATURIA

The amount of blood present may be sufficient to produce a blood-red urine or may be so small that it is detected only on microscopic examination. Since blood cells disintegrate in an alkaline and dilute urine, the specimen should be examined soon after voiding. Hematuria must be distinguished

from hemoglobinuria, in which only blood pigment is present, and from bright red urine containing beet pigment sometimes seen after ingestion of this vegetable. In the newborn, hematuria must be distinguished from the brick-red staining caused by urates.

**Etiology.** Large hemorrhages are most often renal in origin, whereas blood appearing only at the onset or termination of micturition is likely to be from the lower urinary tract. The two-glass test may help determine whether hematuria occurs only during a phase of micturition or throughout the voiding. Blood casts are proof that hematuria is of renal origin. Cystoscopic examination and ureteral catheterization may be necessary to determine the origin.

Among the local causes are glomerulonephritis; pyelonephritis; neoplasms, usually of the kidney; renal tuberculosis; calculus; trauma; renal angioma; hemorrhagic cystitis; chronic infection, with dilatation of ureters which bleed; and chemical and toxic irritants, such as urotropin, turpentine, carbolic acid and the sulfonamides. Thrombosis of the renal and intrarenal veins and bilateral cortical necrosis may produce hematuria, often in association with renal failure. In the newborn uric acid infarction in the kidney can be a cause. A common cause for slight bleeding is ulceration at the meatal opening of the penis produced by irritation of ammoniacal urine; the blood is bright red and appears only in the first few drops of urine passed.

There are numerous systemic causes for hematuria, of which sepsis, especially in the newborn, is a common one. Leukemia, purpura, aplastic anemia and hemophilia are among the blood dyscrasias which may produce hematuria. Scurvy is often manifested early by the presence of a few red blood cells in the urine. Vitamin K deficiency may result in hematuria. Congestive cardiac failure may be a cause. Strenuous physical exercise and exposure to cold may cause a temporary, slight hematuria. In some cases varicosities of the renal vessels have been found. Spontaneous bleeding is sometimes seen in allergic persons, but whether it is an allergic manifestation is not clear.

### AMMONIACAL URINE

In most instances ammonia appears in the urine only after exposure to the air. In some instances, however, the conversion of urea to ammonia is produced almost immediately on passage of the urine. In many infants the ammonia is highly irritating to the skin and often results in varying degrees of dermatitis as well as meatal ulcers.

In long-standing urinary tract infections, including cystitis, the breakdown of urea to ammonia may occur in the bladder. Increased ammonia excretion may also result from increased production of it in the kidney during metabolic acidosis. In the latter instance the urine does not have an ammoniacal odor.

## ABNORMAL PIGMENTS IN THE URINE

For Porphyrinuria and Tyrosinuria, see pages 279 and 258.

### ABNORMALLY COLORED URINE

A red tint may be due to blood, hemoglobin, porphyrinuria or ingestion of beets (*anthrocyaninuria*) or certain dyes. Urates produce a reddish precipitate. Bile may produce a reddish-yellow color. A green or blue urine may be caused by ingestion of methylene blue; purple by fuchsin; magenta by phenolphthalein; red with a greenish fluorescence by eosin; black by ingestion of carbolic acid, in alcaptonuria, or by the presence of melanin; bright yellow by ingestion of carotene-containing foods. Some of these colorations may follow ingestion of certain artificially colored candies.

### HEMOGLOBINURIA

Hemoglobin appears in the urine when blood destruction is too rapid for the reticuloendothelial cells to dispose of it. A positive benzidine test in the absence of red blood cells is diagnostic of hemoglobinuria, but spectroscopic examination offers the most conclusive evidence. In severe hemoglobinuria renal tubular function may be disturbed. Albumin is present in small amount, and hyaline and granular casts are usually found. In some instances the so-called lower nephron nephrosis syndrome develops with rapidly occurring oliguria and renal failure. The urine is light or dark red or reddish-brown, at times almost black. Hemoglobinuria may be caused by hemolytic blood dyscrasias; severe infections; burns; parasitic diseases, such as

malaria; poisoning, as with carbolic acid, potassium chlorate, oxalic acid, arsenic, phosphorus, carbon monoxide, chloroform, quinine, naphthol, aspidium, snake venom and mushrooms; favism; and by transfusion with incompatible blood. Sulfonamides may also cause hemoglobinuria.

Besides removal of the primary cause of the hemoglobinuria, immediate therapy consists in hydration and alkalization.

### PAROXYSMAL HEMOGLOBINURIA

This rare disturbance, a manifestation of late congenital or acquired syphilis, occasionally occurs in childhood. The hemoglobinuria is transient, recurring after exposure to cold and occasionally after exertion. It results from the presence of an autohemolysin in the blood which unites with the red blood cells at low temperatures, leading to rapid hemolysis. The titer of the autohemolysin may show variation from day to day and may persist after the patient has ceased to have paroxysms upon exposure to cold (the *Donath-Landsteiner test*). The attack can be reproduced by immersing an extremity in iced water ( $18^{\circ}\text{C}.$ ). Venous blood withdrawn from the extremity at such a time will contain free hemoglobin. In the spontaneous attack, blood which has been chilled in the peripheral capillaries becomes hemolyzed when it passes to the higher temperature of the internal vessels. Hemoglobinuria occurs when the kidney threshold for hemoglobin is exceeded. With hemoglobinuria there may be chills and fever, prostration, slight jaundice, pain in the lumbar region and such vasomotor symptoms as cyanosis, pallor, urticaria, and coldness of the extremities. There may be no symptoms except the urinary ones. The urine has a dark red or burgundy color. In the freshly voided specimen red blood cells may be found in

addition to the hemoglobin. The erythrocytes in the blood diminish in number during the attack, but rapidly return to normal. There may be a slight polymorphonuclear leukocytosis, a diminished coagulation time and an indirect van den Bergh reaction. The discharge of hemoglobin may last from a few hours to (rarely) one or two days.

The paroxysmal type of hemoglobinuria is not dangerous. *Treatment* consists in rest, warmth, perhaps residence in a warm climate, and antisiphilitic treatment.

*Paroxysmal nocturnal hemoglobinuria* is rarely seen in children.

### MELANURIA

Excretion of melanogen is rare, occurring in some cases of melanotic neoplasms, and has been reported, perhaps incorrectly, in other conditions such as cachexia, pneumonia, intestinal obstruction, and after exposure to roentgen and sun's rays.

### BILE PIGMENTS IN THE URINE

Both urochrome and urobilin are found in normal urine. Urochrome is the chief pigment of normal urine. Under normal circumstances urobilin is taken up by the liver. When the capacity of the liver is reduced or when this pigment is produced in the intestine in amounts the liver cannot handle, the blood level of this pigment rises. It is then excreted in the urine in abnormal amounts. Thus its presence in large amounts in the urine is a sign of liver damage or excessive blood destruction (the primary source of the urobilin). Bilirubin in the urine usually indicates the existence of obstructive jaundice. It may be found in small amounts during various types of hemolytic icterus.

## MALFORMATIONS OF THE URINARY TRACT

Single and multiple malformations of the urinary tract are common in children, being found in 5 to 12 per cent of autopsies. Many of them produce no symptoms or disturbances of function.

The kidneys may be absent, hypoplastic, hypertrophic, duplicated, ectopic, polycystic or fused (*horseshoe*). There may be absence

of one or both ureters; they may be hypoplastic, duplicated, dilated or ectopic; or they may be obstructed by strictures, valves, kinks or abnormally placed blood vessels which cross them at a right angle. The bladder may be absent or hypoplastic, or there may be hemiatrophy of the trigone, exstrophy, a ureterocele or diverticulum. The urachus

may remain patent, or there may be a cyst of it. Fistulas may extend from the bladder to the rectum or the vagina. The urethra may be absent, hypoplastic or obstructed by a stric-

ture, or there may be a hypospadias or epispadias. The urethra may be connected with the rectum by a fistula. These are the most common malformations of the urinary tract.

## MALFORMATIONS OF THE KIDNEY, URETERS AND BLADDER

Malformations which obstruct the flow of urine are the most common types and have the gravest clinical significance. Aside from these, the more important malformations are congenital cystic kidneys, hypoplastic and aplastic kidneys, exstrophy of the bladder and persistent urachal tract.

### RENAL AGENESIS AND HYPOPLASIA

*Bilateral renal agenesis* is a rare condition encountered more frequently in males than in females. The infant is usually stillborn or lives only a few hours, although one infant is reported to have survived for eleven days. The anomaly may be an isolated one or may be associated with other malformations, as with fusion of the lower extremities. The diagnosis may be suspected during life by the peculiar facies, first described by Potter. The distance between the eyes is increased, the palpebral fissures are flattened or even mongoloid in their configuration, and there are prominent epicanthi. The ears are large and low set, and the chin is receding.

*Unilateral renal agenesis* is usually associated with complete absence of the ureter on the affected side, although rarely a patent ureter may be present with a normal trigonal orifice. The single kidney may be pelvic in location and its ureteral orifice open into the midline of the bladder. Malformations of the genital tract are present in over half of the patients, but anomalies involving systems other than the genitourinary tract are less frequent than in patients with bilateral renal agenesis.

*Bilateral renal hypoplasia* may be compatible with life for months to a few years. The manifestations are those of chronic renal insufficiency: stunting of growth, anemia, polyuria with a urine of low, fixed specific gravity, azotemia, hyperphosphatemia, and the osseous changes of so-called renal rickets. The morphologic changes in the kidneys are similar to those in unilateral renal hypoplasia.

Unilateral renal hypoplasia may differ only quantitatively from normal, in which case

the diagnosis is dependent upon the demonstration of decreased numbers of pyramids. Pyelography reveals a small, triangular-shaped pelvis from which emerges only one or two calyces; the appearance may simulate that of the upper portion of a duplicated renal pelvis. The opposite kidney and its pelvis are enlarged. Urine that is apparently normal may pass from the ureter on the affected side, yet death from renal insufficiency follows removal of the larger kidney.

In other instances not only is the hypoplastic kidney decreased in size, but also its histologic appearance is greatly altered. The renal pelvis may be relatively large. Scattered small cysts are present in the affected kidney, which consists of islands of normal or hypertrophic renal parenchyma alternating with areas of fibrous tissue containing small cysts, a few glomeruli and scattered islands of hyaline cartilage. With more advanced degrees of renal hypoplasia the affected kidney may consist entirely of a mass of fibrous tissue containing cysts. The renal pelvis is absent, and the affected ureter is hypoplastic or imperforate; a ureteral orifice, however, is usually present in the trigone.

The *unilateral multicystic kidney* is probably a variant of renal hypoplasia, although the lesion has been referred to as unilateral polycystic disease of the kidney. The presenting complaint is usually that of an abdominal mass which may be thought to represent a Wilms' tumor or a hydronephrotic kidney. The kidney is a large misshapen mass composed of multiple cysts of varying sizes united to each other by loose fibrous tissue. The renal pelvis is usually absent, and the ureter is imperforate.

Pyelonephritis may be the initial manifestation associated with renal hypoplasia, and hypertension is common. Relief of the hypertension has been reported following removal of a unilateral hypoplastic kidney. Although the hypertension may recur after nephrectomy, removal of a unilateral hypoplastic kidney appears to be justified if the opposite kidney is shown to be functioning adequately.

## POLYCYSTIC DISEASE OF THE KIDNEYS

The term "polycystic disease of the kidneys" is frequently applied to any kidney containing multiple cysts. It is preferable, however, to differentiate true polycystic disease of the kidneys from such other lesions as renal hypoplasia with cysts and multicystic kidney. True polycystic kidneys are almost always bilateral; whether unilateral forms ever occur is uncertain, but many which have been reported as such probably represent instances of unilateral renal hypoplasia with cysts or multicystic kidneys. The kidneys are enlarged, but retain their usual reniform shape; rarely the enlargement may be so great as to interfere with delivery of the infant. Myriads of minute cysts are present in the cortex and medulla with a resultant spongy appearance; the cysts may be so minute, however, as to be overlooked on superficial examination of the surfaces of the kidneys. The renal pelvis and calyces are present but distorted because of the increased bulk of the surrounding tissue.

The pathogenesis of polycystic disease is still unknown. Many believe that polycystic disease as encountered in adults is essentially the same as that encountered in infants, but there is suggestive clinical and morphologic evidence that they represent different entities. Tubular cysts encountered in adults communicate with the renal pelvis, whereas those in infants do not; glomerular cysts do not communicate with the pelvis in either infants or adults. Moreover, genetic studies suggest that the infantile form probably is transmitted as a mendelian recessive trait, whereas the adult type occurs as a dominant character.

Other anomalies may occur in infants with polycystic disease of the kidneys, e.g., polydactylism, hydrocephalus and cardiac malformations. Polycystic disease of the liver occurs in 20 to 30 per cent of affected infants; cysts in other viscera such as the pancreas, spleen and lungs occur less frequently.

The clinical manifestations vary with the severity of the process. In severe types death occurs in utero or shortly after delivery and is associated with massive abdominal enlargement. Less severe renal involvement is associated with evidences of chronic renal insufficiency and the presence of bilateral palpable abdominal masses. Severe hypertension may be present even in the first few months of life and may be associated with cardiomegaly and signs of congestive cardiac

FIG. 309. Polycystic kidney disease. Pyelogram shows "spider pelvis" characteristic of this disease.

failure. Hepatomegaly may be present in association with polycystic disease of the liver, and secondary infection may occur both in the renal and in the hepatic cysts. Pyelography characteristically reveals elongation of the renal pelvis and major calyces with flattening of the minor calyces; a variety of patterns may be produced, however, and the roentgenographic findings are not pathognomonic of the disease.

## SOLITARY RENAL CYST

Simple renal cysts are usually solitary and unilateral, but several cysts involving one kidney or bilateral solitary cysts may occur. The presenting complaint is usually that of an abdominal mass. The cysts are usually unilocular and do not as a rule communicate with the renal pelvis. They should be differentiated from polycystic disease of the kidneys, multicystic kidneys, hydronephrosis and Wilms' tumor.

## EXSTROPHY OF THE BLADDER

Exstrophy of the bladder occurs chiefly in boys. When the defect is complete, the entire lower urinary tract from the apex of the bladder to the external urethral meatus is exposed and everted on the abdominal wall. The trigone and the ureteral orifices can be seen in the center of the mass. There is an associated complete epispadias of a short penis; in girls the clitoris may be fissured and the labia separated. In some instances the

exstrophy is not complete, and only a part of the bladder is exposed. The exposed bladder mucosa is bright red, has numerous folds, and is extremely sensitive to touch. With advancing years this sensitivity decreases, and portions of the bladder mucosa are replaced by squamous epithelium. There is a wide diastasis of the rectus muscles below the umbilicus; the pubic rami are widely separated, causing the child to walk with a waddling gait. The testes are usually in the abdomen, and bilateral inguinal hernias may be present. In girls the vagina may be absent or replaced by a cloaca including vagina and rectum. At times there are defects of the lower bowel. These patients are quite uncomfortable. It is difficult to prevent seepage of urine, and there is usually a constant odor of it. The surrounding skin is often badly excoriated, and ulcerations of the bladder mucosa are common. Rarely there are malignant lesions. It is surprising how few of these children acquire infections or obstructions of the urinary tract. Exstrophy of the bladder is not incompatible with a full life span.

When the exstrophy is not complete, a satisfactory plastic closure of the abdominal and bladder walls may be obtained. In a complete exstrophy Ladd recommends implantation of both ureters into the sigmoid, obtaining valvelike ureteral orifices by embedding the ureters for some distance in the intestinal wall before an opening is made into the bowel lumen. The operation is performed in one stage, but not until the child

has attained good anal sphincter control at three to five years of age. In addition, a plastic repair is performed on the bladder and external genitals. The results of this operation have been relatively good. Mild degrees of hydroureter and hydronephrosis are common, but usually tend to decrease after a time; occasionally there is a severe degree of persistent hydronephrosis. Pyelonephritis is not infrequent, but can usually be controlled by antimicrobial therapy. The colon bacillus is the most common infecting organism. Adequate renal function can usually be maintained for many years. The ultimate prognosis depends in great measure on the extent of renal damage from back pressure and infection. The gait usually can be improved by a brace designed to correct the deformity of the pelvic girdle which is associated with this condition.

#### PATENT URACHUS AND URACHAL CYST

In the early embryonic stage the bladder extends to the umbilical region, subsequently descending along the anterior abdominal wall. During this descent the upper portion becomes attenuated to form the narrow tube-like urachus, which later is obliterated. On rare occasions an open lumen persists, permitting discharge of urine into the umbilicus in postnatal life. This type of urachal defect is usually associated with obstruction of the urinary tract below the bladder. In some instances there is only an external communication at the umbilicus, and the rest of the

FIG. 310 Exstrophy of the bladder in a boy 10 years of age. Below the bladder is shown the atrophic penis and, below it, the empty scrotum. There is also a right inguinal hernia.

urachal tract is closed off; in others there is only an internal communication to the bladder, with the remaining tract obliterated. The most common urachal lesion is a blind cyst occurring usually at the upper end of the tract just under the umbilicus and extra-peritoneally.

When the entire urachus is patent, there is a constant flow of urine from the umbilical region. The *diagnosis* can be established by means of dyes excreted through the urine, by chemical analysis of the discharge, and by roentgenography after injection of contrast material into the bladder or into the umbilical opening. The urachal cyst exists as a deep midline swelling below the umbilicus attached to the internal part of the abdominal wall.

Urachal cysts may become infected, and at such times the *symptoms* are those of a midline abscess. The abscess may rupture internally into the bladder or the peritoneum, or externally through the umbilicus.

Urachal cysts should be removed when diagnosed and before infection has occurred. If infection has already occurred, surgical drainage is indicated with subsequent removal of the cyst. Tracts which drain urine should be obliterated by surgical means.

## MALFORMATIONS PRODUCING

### OBSTRUCTION TO THE URINARY FLOW

Though urinary obstruction leading to the production of hydronephrosis is usually caused by a congenital defect within the urinary tract, obstruction is also caused by external pressure as by an aberrant blood vessel on the kidney pelvis or ureter or by a neoplasm (usually of the kidney). Urinary calculi, kinking of a ureter secondary to a prolapsed kidney, inflammatory strictures, neuromuscular lesions of the bladder and/or ureter and extreme phimosis are other causes of obstructions.

Care must be exercised in deciding whether a kidney pelvis is slightly enlarged because of back pressure or is simply within the upper range of normal in size. The absence of evident obstruction below the pelvis and of blunting of the calyces would favor the latter probability. However, when the obstruction is at the pelvic-ureteral junction, there will be no ureteral dilatation below this point. In some instances the pelvis is extrarenal and therefore appears enlarged; or there may be congenital absence of a major calyx, or one calyx may be larger or smaller than the others without having any special significance.

It is advisable to divide obstructive lesions into two groups: (1) those below the bladder and (2) those above it. Since there is dilatation of the structures proximal to the obstruction, the bladder will become dilated and its walls hypertrophied when the obstruction is distal to it, but will be uninvolved when the obstruction is above it. Thus involvement of the bladder is a valuable diagnostic guide.

### OBSTRUCTIVE LESIONS INVOLVING THE BLADDER NECK OR URETHRA

Although a tight phimosis may obstruct the urinary flow, it is rarely a cause of serious trouble. When obstructive uropathy and phimosis coexist, a careful search for another obstruction should always be made. Meatal strictures, inflammatory and otherwise, may rarely cause obstruction.

*Congenital obstructions* in the urethra occur almost solely in boys. Congenital narrowing or partial absence of the urethra rarely occurs. The common anomaly consists of one or two membranous folds with one end attached to the verumontanum and the other usually to the lateral urethral walls. As the urine flows from the bladder, these folds acting as valves are ballooned out, causing a diminution in the urethral orifice. At times an obstruction resembling an iris diaphragm may partially or completely encircle the posterior urethra below the verumontanum. There may be some difficulty in establishing the presence of urethral valves, since often there is no obstruction to the passage of a urethral catheter into the bladder. A less common obstruction of the neck of the bladder results from a shelf or bar of hypertrophied muscle on the floor of the bladder at its junction with the posterior urethra. There is some evidence that this lesion is progressive and may not produce serious obstruction during infancy. Prostatic hypertrophy is an infrequent cause of urinary obstruction; transient prostatic hypertrophy causing urinary obstruction has been noted after hormonal therapy for cryptorchism.

In some instances of bladder and ureteral dilatation with hydronephrosis *no obstructive lesion can be found*. Probably these cases belong to the group of neuromuscular dysfunctions. In some of them there are demonstrable lesions of the spinal cord with or without an associated spina bifida. In approximately half of sixty children with megaloureters and megalobladder Swenson and Fisher found a diminution in ganglion cells in the bladder wall and have termed the condition aparasympathetic bladder. These patients

seem to have a loss of sensation in the bladder, but are not incontinent. In contrast to the sex differences in the incidence of obstructive lesion within the lower urinary tract, these cases occur as often in girls as in boys. Slight enlargement of the renal pelvis and widening of the ureters are occasionally seen in infections of the urinary tract without evident obstruction below.

When infravesicular obstruction is of long standing, the bladder may become greatly enlarged, the muscular wall extremely hypertrophied, and the bladder mucosa thrown into innumerable folds. At times diverticula are present. An irregular appearance of the bladder contour may be seen at cystoscopic examination or roentgenographically when no diverticula can be demonstrated; normal bladders may occasionally show some distortion of contour. At times distortion of the bladder contour may result from pressure of an overdistended bowel or an abnormally placed uterus. The persistence of an enlarged bladder after the patient has just voided is suggestive of residual urine in a hypertrophied bladder, indicating obstruction to the urinary flow; this supposition should be tested by a postvoiding catheterization.

#### OBSTRUCTIVE LESIONS INVOLVING THE URETEROVESICAL JUNCTION, URETER, PELVIS OR KIDNEY

Anomalies involving the ureters are the most common ones of the urinary tract. Complete or partial absence of one or both ureters may occur. Duplication, complete or partial, of one or both ureters is fairly common; the duplication may be limited to the renal pelvis. Partial obstruction of the ureter, usually due to a narrowing of the lumen, occurs most often at the pelvic-ureteral and the vesico-ureteral regions; it may occur where the ureter crosses the iliac vessels. In any of these locations the narrowing of the lumen may be due to an inflammatory stricture, a congenital anomaly or compression of the ureter from without, as, for example, by an aberrant blood vessel near the pelvic-ureteral junction.

The obstruction may be a fold in the mucosa at the vesical orifice or an extreme narrowing at the orifice so that there may be ballooning of the ureteral wall into the bladder, producing a *ureterocele* or intravesical cyst of the ureter. This anomaly, which is really a prolapse of the ureter, may be unilateral or bilateral. When the intra-

vesical portion is large, it may result in complete blockage of ureteral urine flow and secondary hydronephrosis. In the early stages correction can often be obtained by endoscopic incision or amputation; when there is significant renal damage, partial or complete nephrectomy and ureterectomy are indicated for the unilateral lesions.

*Diverticula* of the ureters are rare; they may be responsible for obstruction and may be difficult to demonstrate. Retrograde urography would appear to offer the best chance of detection.

The mechanism producing the so-called *megaloureter* (great lengthening and tortuosity of the ureter with greatly thickened walls and hydronephrosis, but without an obstructive or apparent neurologic lesion) is not understood. Occasionally megaloureters occur in association with congenital aganglionic megacolon. Swenson and Fisher noted some defect in bladder function in approximately 50 per cent of their patients with megacolon. In about 3 per cent of them they could demonstrate a megalobladder and megaloureter with evidences of urinary retention. They have attributed these anomalies to a defect in parasympathetic innervation.

Hydroperitoneum has been observed in the newborn in association with congenital obstructive lesions of the urinary tract. Obstruction of the urethra has been the lesion most commonly found.

#### HYDRONEPHROSIS

Dilatation of the kidney pelvis and calyces is due to obstruction in their drainage mechanism. Rarely obstruction of the renal pelvis results from displacement of a movable kidney. If the obstruction is infravesicular, then the hydronephrosis is bilateral (Fig. 311) and develops somewhat more slowly than when the obstruction is supravesicular. Several years may elapse before maximal dilatation is obtained. If there are obstructive lesions in both ureters, the hydronephrosis is also bilateral. If only one side is obstructed, then the hydronephrosis is unilateral (Fig. 312). If the obstruction produces back pressure in the ureters, they become dilated, at times thickened, and, often, increased in length with great tortuosities. In long-standing lesions the renal substance is greatly atrophied as a result of the pressure on the tissues and their blood supply, and the kidney

FIG. 311. Hydronephrosis. Reflux pyelogram showing bilateral hydronephrosis and hydroureters and enlargement of the bladder secondary to obstruction produced by a congenital valve anomaly in the posterior urethra.

may ultimately consist of a thin-walled cystic mass with little functioning renal tissue. The calyces appear on the urogram as large balls, and there may be little or no renal tissue separating them. At times the combined mass of a unilateral hydronephrotic kidney and dilated ureter will produce a large cystic tumor filling half or more of the abdominal cavity. A history of an abdominal mass fluctuating in size and associated with changes in urinary volume is suggestive of hydronephrosis secondary to obstructive uropathy.

**Clinical Manifestations.** The symptoms resulting from obstructive uropathy can, in general, be divided into three categories: (1) interference with the flow of urine, (2) infection, and (3) renal insufficiency.

**Symptoms resulting from interference with the flow of urine.** In *infravesicular obstruction* or with *primary bladder dysfunction* these symptoms are more striking than when the obstruction is above the bladder. The presenting symptom is often an abdominal tumor (distended bladder) noted by the mother. There is a thin, weak urinary stream, which is projected for only a small distance, or a continuous dribble. There may be some hesitation or difficulty in starting the urine flow and even periodic inability to void at all. It is important to question the mother about the voiding habits of the child and especially to watch the child void. Residual bladder urine can be demonstrated by catheterization,

but only immediately after a voluntary voiding.

In the so-called *cord bladder* there may be complete paralysis with overflow incontinence. Reflex automatic voidings usually develop with associated dribbling. In supralumbar lesions this type of voiding may be reasonably efficient, but residual urine still remains in the bladder. Relaxation of the rectal sphincter is usually an associated lesion. In so-called *aparasymphetic megalobladders* the defect in function is said to be less pronounced than with cord bladders, and incontinence does not occur.

In *supravesicular obstruction* symptoms referable to the urinary tract may be entirely lacking. In some instances there may be intermittent periods in which large quantities of urine are voided, owing to the release of an obstructed and greatly distended ureter and/or a hydronephrosis. Many of these children complain of vague or even severe colicky abdominal pains variously referred to the renal region or midanterior area of the abdomen. The pain may also radiate to the groin or thigh and resemble a Dietl's crisis. Large masses which may give the impression of being cystic are often palpated in either or both flanks. The distended bladder can be palpated above the symphysis even after urination.

In very young infants with relaxed abdominal walls the kidneys can normally be palpated. This examination is best conducted bimanually with one hand pressing upward in the flank and the other downward over the anterior abdominal wall. When the kidneys are easily palpable or appear at all enlarged, a thorough urologic study is indicated (see below).

**Symptoms resulting from infection.** (See p. 1032.) Irregular bouts of fever, with or without chills, or convulsions in the young infant are commonly present. Intermittent or persistent pyuria, microscopic hematuria and rarely gross hematuria occur. In some long-standing cases, even though the renal substance is infiltrated with small round cells (old infection), the urine finally becomes free of pus cells and bacteria. There may be malaise and, in long-standing cases, cachexia. Children whose malnutrition is not readily explainable on other grounds should have a thorough examination of their urinary systems.

**Symptoms of renal insufficiency.** The third category of symptomatology is manifest

by progressive renal dysfunction, death resulting from renal failure. Pyuria may or may not persist, casts and red cells are often present, and the urine, which is increased in volume, has a fixed, low specific gravity. The nonprotein nitrogen of the blood is increased, the blood pressure is elevated, and there is a state of acidosis with which there may be a relatively alkaline urine (pH above 6). All phases of renal function are reduced. The blood inorganic phosphorus may be elevated and the calcium reduced, resulting in tetany, renal hyperparathyroidism and dwarfism with the characteristic bony deformities of renal rickets.

The suspicion that a congenital malformation of the urinary tract exists should lead to immediate urologic study. The simplest methods are urinalysis, measurement of the blood urea nitrogen, cystography and intravenous urography. Cystography will often

demonstrate an infravesicular obstruction with reflux into the dilated ureters, either by hydrostatic pressure or during voiding. The child should be tested for sensitivity to the contrast material to be used for intravenous urography before it is injected intravenously. In some instances intravenous urography will fail to demonstrate a congenital defect, and retrograde urography is required. When it is desired to determine whether the renal involvement is unilateral or bilateral, renal function tests of each kidney should be performed. Cystometric studies and studies of ureteral peristaltic activity may be helpful in evaluating the lesion and gauging prognosis.

**Treatment.** The treatment of obstructive uropathy is that of renal insufficiency and infection, when they exist, and relief of the obstruction. Since the sudden release of urine from a greatly distended bladder may result

FIG. 312. Congenital obstruction at the ureteropelvic junction due to fibrosis of the ureteral wall. An anomalous renal artery crossed the ureter at this point and may have precipitated these fibrotic changes. A, Kidney removed at operation. Note the stricture at the ureteropelvic junction and the greatly dilated renal pelvis and calyces. B, Intravenous urogram showing normal right renal pelvis. The left renal pelvis is not visualized, probably because of poor renal function and great dilution of the Diodrast. C, Retrograde pyelogram showing greatly dilated calyces on the left side which were not visualized at all in the intravenous urogram (B).

in shock and even fatal anuria, the bladder should be emptied by gradual decompression through an indwelling catheter. A rapid improvement in renal function often follows this drainage, even in cases of long-standing obstruction. In the so-called aparasympathetic bladders the patient must be taught to make sustained effort to empty his bladder completely; the aid of manual suprapubic pressure is often necessary. A schedule of four or five voidings a day and one or two at night can be recommended. Resection of the bladder neck may be necessary to relieve urinary retention.

Other obstructive lesions are also amenable to surgery, but before operation is attempted the patient's general condition should be improved as much as possible and the urinary tract infection brought under control. Even though considerable renal function has been lost, with the present means of controlling infection surgical relief should be attempted. Useful life is compatible with a considerably lowered renal function, and it is often surprising to what extent the renal function will improve after an obstruction is relieved. In the mild cases there may be an almost complete restoration of the urinary tract to normal size and a complete recovery of renal function. In more advanced cases less anatomic and functional recovery occurs, but even in those cases in which there is extensive renal destruction little is to be lost in trying surgical treatment.

### DISPLACEMENT OF THE KIDNEY

**Dystopia.** Accompanying or independent of some of the malformations described, the kidney, especially the left, may occupy a position lower and nearer the midline of the body than normal. On palpation this may cause confusion with such conditions as intussusception, fecal accumulation and ap-

pendicitis. There may be no symptoms, or the kinking of the ureter may cause pain and dysuria, and lead to hydronephrosis.

**Movable Kidney.** This relatively uncommon condition may be congenital or acquired. The acquired form is seen oftener in girls than in boys during late childhood and may result from pressure by tumors or from trauma. *Symptoms*, if present, are a sensation of pressure or dragging in the abdomen or lumbar region, attacks of renal colic (Dietl's crisis) and perhaps chronic urinary tract infection. General splanchnoptosis may also be present. Hydronephrosis may develop from kinking or twisting of the ureter. In establishing a *diagnosis* it should be remembered that it is often possible to palpate the lower pole of the kidney in normal children. Intravenous pyelography in the supine and upright positions will usually establish the diagnosis, but retrograde pyelography is necessary at times. *Treatment* consists in efforts to retain the kidney in position by a pad or bandage. Surgical measures are seldom required.

## INFECTIONS OF THE URINARY TRACT

### PYELONEPHRITIS, PYELITIS

Acute infections of the urinary tract are relatively common in pediatric practice. Such infections are rarely limited to a single portion of the urinary tract, and for this reason the term "pyelitis," commonly applied, is scarcely applicable. Infections of the renal pelvis usually extend into the renal paren-

chyma, producing a pyelonephritis, and there is usually some associated inflammation of the ureters and bladder.

Acute infection of the urinary tract may be suspected from the clinical symptoms (often there is none related directly to the urinary tract), but the diagnosis is established only by demonstration of pus cells and bacteria in the urine, whose origin is not

from an extraurinary source such as a vaginitis or "container contamination."

**Etiology.** The incidence of acute pyelonephritis is highest during the diaper age, being somewhat less during the first few weeks of life than during the remainder of infancy. Pyelonephritis represents the most common renal disease of childhood, and in its chronic forms is the most common cause of chronic renal failure. It occurs about six times as frequently in the female as in the male, except during the neonatal period, when there is about an equal incidence. There is some experimental and clinical evidence that a lowered tissue resistance of the urinary tract predisposes to infection. Many different bacteria infect the urinary tract, but the colon bacillus group is responsible for about 80 per cent of all cases. Less frequently the *Staphylococcus*, hemolytic *Streptococcus*, *Streptococcus faecalis* and still less commonly other organisms such as those of the *Proteus*, *Pseudomonas*, typhoid, *Salmonella* and dysentery groups and tubercle bacilli are etiologic.

In chronic pyelonephritis the colon bacillus accounts for relatively few infections, and multiple bacterial infections are common. *Proteus* and pyocyaneus are common infecting bacteria in chronic infections associated with urinary obstruction and in patients who have had many recurrent infections and considerable antibiotic therapy. Though some of the infections, especially the coccal forms, reach the kidney by way of the blood stream from a distant focus, there is evidence to suggest that the larger number of infections ascend by way of the urinary tract to the kidney through the urinary stream by regurgitation or through the lymphatic channels, and that infection from the renal pelvis spreads throughout the kidney by way of the perivascular or vascular routes. The observations that the colon bacillus is an unusual blood stream invader, that the incidence of pyelonephritis is highest in the diaper age, that it is more frequent in girls whose urethra is short and more often infected from fecal contamination add support to the belief that infections of the urinary tract most commonly occur by the ascending route rather than by the hematogenous one.

Stasis from congenital malformations is the most common cause of chronic urinary tract infections, being present in about 75 per cent of them. Rarely the tract may be obstructed by a calculus or foreign body or by a neoplasm of, or adjacent to, the urinary tract.

The presence of a neurologic bladder may impede the flow of urine. Once infection is established it is difficult to eradicate it unless adequate urinary drainage is obtained. Hence there is danger from infection after the catheterization of patients with obstruction of the bladder neck. Occasionally pyuria results from rupture of an abscess into the urinary tract. The proximity of an inflamed appendix to the right ureter has also resulted in pyuria.

**Pathology.** Infection and inflammation are rarely limited to the renal pelvis (pyelitis); most often there are also inflammatory changes irregularly distributed throughout the kidney mass. The majority of cases which come to autopsy are associated with obstructive lesions of the urinary tract.

In the mild cases there are congestion and leukocytic infiltration in the renal pelvis, and small hemorrhages may be present. In the interstitial spaces and in the tubules are collections of polymorphonuclear cells and, in the chronic form, lymphocytes. The capillaries are dilated, and hemorrhage may be seen throughout the interstitial tissue as well as in the tubules. In the more severe, acute forms miliary abscesses occur throughout the parenchyma; the kidney may be greatly swollen, and clumps of bacteria may be present.

When the infection has been prolonged, there are often extensive areas of scarring with loss of functional renal parenchyma. The end result may be a small, shrunken kidney. In such long-standing cases active infection may have ceased, and bacteria and pus may have disappeared from the urine. Many of the nephrons undergo complete degeneration and finally disappear; the remaining tubules are dilated and filled with coagulated protein. Calcium deposits may be present in lesions of long standing. Arteriosclerosis and arteriolosclerosis may be present in association with chronic pyelonephritis.

In most instances some degree of inflammatory reaction is seen in the submucosa of the ureters and bladder. In long-standing infection secondary to infravesicular obstructive anomalies the bladder and ureters may be dilated and their walls greatly thickened. Infection itself is said to produce some dilatation of the kidney pelvis and ureter. Whether the dilatation is caused by blockage or by weakening of the walls from infection is not known. Occasionally inflammatory thickening of the ureter is responsible for urinary obstruction with proximal dilatation of the ureter and pelvis. With subsidence of infec-

tion in such cases it is possible that the ureter and pelvis may return to their normal size. With long-standing obstruction of the urinary tract the renal tissue may be compressed into a thin shell surrounding the greatly dilated calyces (Fig. 312). With increasing destruction of renal tissue, renal function progressively fails.

**Clinical Manifestations.** Typically in *acute pyelonephritis* the onset is abrupt with fever, the child appearing acutely ill. The temperature not infrequently reaches  $103^{\circ}$  to  $105^{\circ}$  F., but is rarely sustained at such levels for over a day or two; characteristically there are wide fluctuations. On occasion there may be little or no fever.

In the infant there are usually no localizing signs to indicate that the infection is in the urinary tract, except perhaps for urinary frequency, which is difficult to evaluate at this age. During the period of high temperature the infant is likely to be irritable, and other central nervous symptoms such as convulsions and meningismus may be manifest. Prostration may be great. Gastrointestinal manifestations are common, vomiting often being a striking symptom. It may be projectile, associated with exaggerated gastric peristaltic waves and persistent enough to simulate pyloric stenosis. Diarrhea occurs occasionally, as it may with other infections during early life, and may result in dehydration. Anorexia is usually marked.

In older children there may be localizing symptoms. When there is an associated cystitis, frequency of urination, urgency and dysuria may be present. Not infrequently there is pain, sharp or dull, over the renal area with muscular spasm and tenderness on palpation. It cannot be overemphasized that at any age all symptoms may be lacking or none may be related to the urinary system, and the diagnosis is established, if at all, by urinalysis and culture.

In most untreated cases the fever lasts seven to ten days and the urinary changes about three weeks. The acute clinical manifestations usually last for only the first few days of the disease. Pallor, anorexia and failure to thrive, however, may persist for weeks after the urine has returned to normal if the kidney lesion remains active. In the unusual, severe form when large areas of the kidney are abscessed, there is great intoxication; in such infections death may occur within a week or two after the onset of the illness. The fatality rate, however, is low among the ordinary acute cases.

*Chronic infections* present the more serious problems. Instead of subsiding after two or three weeks, as most often happens, the infection may persist for months or years with intermittent fever, pyuria and progressive involvement of the renal parenchyma leading to interference of renal function and to hypertension. The principal symptoms are inanition, anemia and failure to grow, but acute exacerbations are common. During early childhood a not too restricted life is compatible with a greatly reduced renal function, which finally fails, producing uremic symptoms, often during periods of rapid growth, as in puberty. In many instances, although the infection becomes quiescent or is "burnt out" and pus and bacteria no longer appear in the urine, the kidney is chronically scarred and contracted and there is a persistent decrease in renal function. Since the manifestations of the renal insufficiency are not unlike those of chronic nephritis, the true etiology of the renal lesion may be overlooked unless a past history of pyuria is obtained or a congenital malformation of the urinary tract is demonstrated. In unilateral chronic pyelonephritis renal function may not be significantly reduced, owing to hypertrophy of the nonaffected nephrons in the diseased kidney and in the uninfected kidney. Loss of renal concentrating capacity, however, is a common feature of persistent pyelonephritis and may occur early. Secondary hyperparathyroidism may be a complication. Hypertension may be marked and may be responsible for cardiac failure or cerebral hemorrhage. Since chronic infection is commonly associated with obstructive lesions of the urinary tract, persisting symptoms may be referable to urinary obstruction and renal failure (see p. 1028).

**Diagnosis.** The diagnosis is based upon demonstration of pus and bacteria in the urine. Urine is normally sterile, but is readily contaminated during and after voiding. Urine contains a small number of white blood cells under normal circumstances. Addis counts of healthy children (voided in boys, catheterized in girls) demonstrate between 1,000,000 and two million white blood cells in the urine excreted in a twelve-hour period. In a fresh, uncentrifuged specimen obtained by similar means there should not be more than one or two white blood cells per low power microscopic field, or a freshly shaken specimen should contain not more than one cell per 10 high power fields. The most common source of pus in the urine is from vaginal secretions, and many girls are treated for

months for a so-called pyelitis when the origin of the pus cells is in the vagina. Thus when pus cells are found in the urine, a "clean" specimen should be obtained after thorough bathing of the genitals with soap and water. In boys the foreskin should be retracted and the glans cleansed. If possible, only the latter portion of the voiding should be collected. If this specimen also contains pus cells, then a catheterized specimen should be obtained. Only catheterized specimens are suitable for bacterial culture, and even here the first few drops should be discarded.

It is important to recognize that bacteria may be present in abundance in the urine in the absence of pyuria; bacterial culture in the absence of pyuria may identify a focus of infection. However, isolation of a few bacteria in a catheterized specimen from girls or a mid-stream voided specimen from boys is not diagnostic of urinary infection. Infected urine usually contains more than 100,000 bacteria per milliliter; counts lower than this may represent contamination, suppressive therapy, rapid excretion (not permitting sufficient time for bacterial multiplication in bladder), acid urine with pH below 5.5 or an alkaline urine above 8.5. Certain organisms as group A streptococci, some strains of staphylococci and enterococci may grow poorly in urine and thus produce few bacteria.

The direct examination of a cleanly voided specimen of urine, even in girls, gives a reasonably reliable indication of urinary infection. The absence of bacteria in a fresh drop of urine stained with Gram's stain is strong evidence against the existence of urinary infection. The presence of bacteria in such preparations is usually associated with bacterial counts of 100,000 per milliliter or more.

The external vaginal orifice and the surrounding perineum must be thoroughly cleansed before collecting urine for slide examination or culture; pHiso-hex or Zephiran 1:1000 is used for this purpose.

During the first two or three days of the disease while the fever and associated symptoms are most severe the urine may be normal. Pyuria may be intermittent, especially in chronic infections, but also in acute ones. Initially the absence of pyuria may be due to failure of the interstitial pyogenic collections to rupture into the renal tubules; subsequently temporary absence of pyuria may be due to ureteral obstruction in a unilateral infection. In some instances the urine may be

grossly cloudy, but usually is clear. If the child's dietary intake has been restricted or if there has been persistent vomiting, there may be acetonuria. The urine most often contains a few red blood cells and on rare occasions may be grossly bloody. In the more severe cases granular and hyaline casts may be present. There is a mild anemia, more severe in the graver cases, and a varying degree of polymorphonuclear leukocytosis.

In every instance of persistent or recurring pyuria of urinary tract origin the child should be examined by intravenous and, if necessary, retrograde urography in search of structural or neurologic abnormalities which might be responsible for stasis and thus for persistence of an infection. The use of the cystogram provides a relatively simple method to examine the child for ureteral dilatation, which is not disclosed by intravenous urography. When there is no spontaneous reflux into the ureters with the upper half of the body lowered, there may be reflux during voiding, the so-called voiding cystogram.

**Treatment.** Though most acute urinary tract infections heal spontaneously, it is advisable to treat them with an antibacterial agent in order to shorten the course and to attempt to avoid the infrequent instances of progressive renal damage. Other aspects of therapy include bed rest during the febrile stage and sedative and/or analgesic drugs only when necessary to secure rest or relief of pain. In acute cases the intake of fluids should not be restricted, since the chance of renal infection is increased when urinary output is diminished. In all instances of persistent urinary tract infection urographic studies are indicated to determine whether there is an obstructing anatomic lesion; an intravenous pyelogram may be the only procedure necessary.

The selection of the antibacterial agent in the acute cases should be based whenever possible on the establishment of its effectiveness against the invading organism. Such information is essential in all chronic infections when antibacterial therapy is used as an adjunct to measures designed to eliminate any anatomic variants or neurologic dysfunction which may contribute to persistence of infection.

The sulfonamides are perhaps the antibacterial drugs most widely used for urinary tract infections. They are effective against many of the common pathogens of the urinary tract, and bacterial drug resistance is not rapidly established. Sulfadiazine, sulfa-

merazine and sulfisoxazole (Gantrisin) are all effective. Gantrisin has the advantage of being more soluble and hence is somewhat less likely to produce crystalluria. Combination of two or more sulfonamides in total doses equal to that for a single agent is another means for decreasing the production of crystalluria. Effective doses of the sulfonamides are in the range of 0.1 to 0.2 gm. per kilogram of body weight per day in four to six divided doses. In a few instances the dose may need to be increased, and often in the case of drug-resistant bacteria better results can be obtained by the combination of a sulfonamide and an antibiotic chosen on the basis of effectiveness demonstrated *in vitro* against the bacterium in question. In the treatment of chronic or complicated infections the sensitive organisms may be eliminated and be replaced by resistant bacteria.

Nitrofurantoin (Furadantin) is bacteriostatic and bactericidal against most of the pathogens of the urinary tract; strains of *Proteus* and *Pseudomonas* are relatively resistant. It is contraindicated during oliguria or with severe renal damage. Blood cell counts should be made periodically during prolonged therapy to watch for possible hematopoietic suppression. (See p. 217 for dosage.)

Mandelic acid (calcium mandelate or mandelamine, p. 219) has been of limited usefulness in the control of chronic urinary infection because it is effective only in the presence of an acid urine, which was difficult to maintain by available methods. Recently Kass has been able to maintain the urine at a pH 5 over a period of months by oral administration of methionine. At this pH he has found mandelic acid an effective antibacterial agent for such organisms as *Proteus*, *Pseudomonas*, the coli group and staphylococci even when the commonly used antibiotics have failed. In cases in which complete sterilization has not resulted there has been a decrease in the bacterial count. Kass uses the urinary pH (nitrazine paper, pH of 5) as an indication of the amount of methionine needed. In general a sufficiently low pH has been obtained with 1 gm. of methionine per 5 kg. of body weight per day. Voided bacterial counts less than 100,000 colonies per cubic centimeter are used as an indication of the effectiveness of mandelic acid and the amount of it to be prescribed. Kass has also used hippuric acid as an antibacterial agent in a similar manner with gratifying results.

Antibacterial therapy should be continued until the patient is afebrile and two sterile

urine cultures are obtained at an interval of three days. After the therapy has been discontinued the child should be re-examined (including a urinalysis) at intervals of a week and a month to detect any recurrence.

## PERINEPHRITIS

### (PERINEPHRIC ABSCESS)

Perinephritis is an inflammatory reaction in the soft tissues surrounding the kidney. The infection is usually unilateral and usually proceeds to suppuration unless checked by therapy. Pus accumulates below the kidney and may extend in any direction, usually along the lumbar muscles toward the pelvis. It may rupture into the iliocostal space, above Poupart's ligament, or into the peritoneum, intestines, kidney, bladder or pleura.

**Etiology.** Perinephritis may follow trauma over the renal area, it may be blood-borne from suppurative infections elsewhere, or it may be a direct extension from a neighboring focus. Staphylococcal infections of the skin frequently antedate the renal infection. In the majority of instances infection of the perinephric space results from rupture of an embolic renal cortical abscess.

**Clinical Manifestations.** The symptoms come on abruptly with fever, chills and other signs of acute infection. The fever is usually remittent. Signs localizing the disease to the renal region appear early with pain in the lumbar region of the affected side which may be referred to the groin, hip, thigh or knee. Movement of the spine causes discomfort, so that the patient walks with difficulty or prefers to lie on his back and, because of the spasm of the iliopsoas muscle, keeps his thigh flexed. Extension of the flexed leg is resisted, owing to the induced pain, but movement of the hip and knee joint in other directions is unhampered. Locally, there is tenderness with muscle spasm over the renal area and eventually an indefinite swelling, at times with demonstrable fluctuation. The overlying skin and subcutaneous tissues may become reddened and edematous.

Urinary symptoms are usually lacking, although in about half of the cases there is pyuria during the course. Often a bulging psoas shadow can be seen on the roentgenogram, and elevation and decreased excursion of the diaphragm are evident during fluoroscopy. Acute cases may terminate within several weeks with gradual subsidence of all symptoms and signs; or the infection may become chronic and persist for months with

final resolution or with rupture of the pus into one of the areas mentioned.

**Prognosis and Treatment.** The prognosis is influenced by the primary disease. Treatment consists in rest in bed, local application of heat during the early stages, administration of an appropriate antibiotic, and, if suppuration occurs, surgical drainage. Blood and urine cultures may aid in establishing an etiologic diagnosis and thus permit a more effective selection of the antibacterial agent.

## DISTURBANCES OF THE KIDNEY

### NEPHRITIS

(BRIGHT'S DISEASE)

#### ACUTE GLOMERULONEPHRITIS

(ACUTE HEMORRHAGIC NEPHRITIS)

Glomerulonephritis is largely a disease of childhood and is the most common form of nephritis in children. Its true incidence is not known, since many of the milder cases are unrecognized clinically; it accounts for about 0.5 per cent of hospital admissions. About two thirds of the cases occur in children under seven years of age. It is uncommon under three years of age, but it has been observed in the newborn period and as a congenital lesion. It seems to be more common in boys than in girls. In contrast to the chronic vascular forms of nephritis, there is little familial susceptibility.

**Etiology.** Acute glomerulonephritis apparently is an antigen-antibody reaction secondary to an infection elsewhere in the body. Like rheumatic fever, this infection is most often in the upper respiratory tract (occasionally on the skin) and most often is caused by a group A beta hemolytic *Streptococcus*. Not all strains are nephritogenic. Type 12 appears to be the most common of the nephritogenic strains, and types 4 and 25 somewhat less common. The rate of renal involvement in infections with the so-called nephritogenic strains also appears to vary in different epidemics. Nephritis occurs in about

1 per cent of cases of scarlet fever. The onset of nephritic symptoms occurs one to three weeks after the onset of the streptococcal infection. Other organisms such as the *Pneumococcus*, *Staphylococcus* and viridans strains of the *Streptococcus* have also been thought to be infrequent etiologic agents.

Focal nonsuppurative glomerulonephritis may occur at the height of a variety of infections and may be associated with sulfonamide reactions. The proteinuria and hematuria in these conditions are usually transient.

Climate plays little part. The incidence of glomerulonephritis, unlike that of rheumatic fever, is the same in both the northern and southern parts of the United States. The rarity of second attacks is probably dependent on the type-specific immunity induced by the infecting *Streptococcus* and the relatively few nephritogenic strains.

See also Nephritis in Schönlein-Henoch purpura (p. 921).

**Pathology.** In acute glomerulonephritis the kidneys are slightly enlarged, pale and dotted with small punctate hemorrhages on the cortical and cut surfaces. Histologically, the endothelial cells of the glomerular capillaries show swelling and proliferation, which obstructs the flow of blood. The epithelial cells of the capsules and of the tufts are also proliferated, and polymorphonuclear cells and monocytes may have infiltrated the glomeruli. The usual appearance is that of large, dark-staining, relatively avascular

glomeruli. Albuminous fluid, red blood cells and white blood cells escape into the capsular space and into the tubules. Fibrin is deposited in the capsular space, leading to adhesions between the capillary tuft and capsular wall. The cells of the tubules are swollen and granular, and contain hyaline and fatty deposits. The interstitial tissues tend to be edematous and congested with a minimal amount of inflammatory cellular reaction. When acute glomerulonephritis heals, there may be no residual evidence of the disease.

In subacute glomerulonephritis the kidney is large and pale. Histologically, there is disappearance of some nephrons, whereas others have undergone a compensatory hypertrophy. The remaining glomeruli reveal changes similar to those described, but often with more numerous capsular adhesions; proliferation of the epithelial cells of the capsule leads to the formation of epithelial crescents. Although some of the glomeruli have become completely hyalinized and their associated tubules have undergone atrophy or have disappeared, the hypertrophy and dilatation of the remaining nephrons prevent actual shrinkage of the renal mass. Focal areas of lymphocytic infiltrate are present in the areas of atrophic renal parenchyma.

It is not always possible to correlate the clinical picture with postmortem renal changes. Electron microscopic studies of renal tissue obtained during life by needle biopsy give promise of providing correlative information.

Though it is postulated that capillary damage in glomerulonephritis is not limited to the kidney, there is little anatomic evidence of it. In some organs other than the kidney small extravascular collections of red cells appear. The occasional finding of petechiae in the skin, the early generalized edema (before cardiac failure occurs, while the serum albumin is at good levels, and in the presence of a good urinary output) and the high protein content of this edema fluid are suggestive evidences of the presence of widespread capillary damage. Cerebral edema is present in some cases; its exact cause is not clear. It may depend on vascular injury, as does the edema elsewhere. In some instances its presence is correlated with a high venous pressure associated with cardiac failure.

Cardiac involvement, as demonstrated by the electrocardiogram, by enlargement on physical and roentgenographic examination or by signs of congestive failure, occurs in

many of these patients and may be an early finding. Little is known about the pathologic lesions in the heart.

**Clinical Manifestations.** There is great variability in the clinical patterns of glomerulonephritis. The attack may be so mild as to go unnoticed or to be detected only by continued clinical observation with recording of temperature and by urinalyses after a streptococcal infection such as scarlet fever. At the other extreme the onset may be abrupt and severe, and there may be some or all of the following: high fever, severe headache, malaise, oliguria to anuria, hypertension with encephalopathy, and cardiac decompensation. Death may occur during such acute episodes. The clinical pattern of the average case is sufficiently characteristic to permit its description.

As a rule the child is not very ill. The most frequent presenting symptom is hematuria. The parents have usually forgotten the preceding acute respiratory infection, and the history of it is elicited only by direct questioning; at times, however, the respiratory infection is still present when the hematuria appears. In some cases puffiness about the eyes antedates the onset of the hematuria or appears coincidentally with it. For the first few days the urine is grossly bloody (at times there is only microscopic hematuria), then acquires a smoky, dirty, brownish hue. Edema may be generalized, but severe edema is usually not seen in acute glomerulonephritis except when fluids have been forced in the presence of oliguria and during cardiac failure. The temperature may be as high as 103° to 104° F. for three to five days, then gradually falls to about 100°, fluctuating at this level for weeks or until the renal lesion has healed entirely. At times there are such gastrointestinal symptoms as loss of appetite, vomiting and constipation; less often, diarrhea. Some patients complain of headache. When the child does not appear acutely ill, it is difficult to impress upon the parents the seriousness of the illness.

On examination little may be found other than a residual upper respiratory tract infection or slight puffiness about the eyes. Varying degrees of hypertension may be present. When the blood pressure is elevated, the pulse rate is slow if the cardiac action is good. The urine is usually decreased in amount, of a high specific gravity, and contains albumin, varying amounts of red blood cells, some white blood cells, and hyaline, granular and cellular casts. The level of blood urea nitrogen is

usually elevated. There is an inverse relationship between the urinary volume and the elevation of the blood urea nitrogen. There is a similar relationship between the urinary volume and the acid-base balance, the severity of the acidosis being directly related to the degree of oliguria. Such a relationship holds for all the waste products excreted by way of the kidney. A slight decrease in the serum albumin, however, is usual. Anemia tends to develop quickly, and the corrected erythrocyte sedimentation rate is rapid.

Some abnormality can be detected on serial electrocardiograms in about 75 to 80 per cent of the cases. In about 50 per cent the heart will be enlarged, and there is evidence of failure in about 20 per cent.

Improvement, manifest by abatement of the constitutional symptoms, usually begins within one to two weeks after the onset, and grossly visible blood disappears from the urine about this time. As a rule the blood pressure returns to normal after about a week, and the blood chemical findings during the second week. Diuresis usually commences after three or four days, and the patient may lose 5 to 7 pounds even though no clinical edema is evident.

Microscopically, the urine returns to normal in an average of about six weeks. Several urinalyses are necessary to establish the cessation of the disease, since red blood cells may be absent and reappear subsequently. Occasionally gross hematuria returns after having temporarily subsided for a few days. When a more delicate test, such as the Addis count, is used, abnormal numbers of red blood cells appear in the urine for about four months in the average case. Thus, though the average patient is usually well clinically within about two weeks, he still has diseased kidneys for about four months. In rare instances complete clearing of the urine may not occur for a year or more.

The erythrocyte sedimentation rate can be used as a measure of the progress of the disease. It remains rapid in the average case for about three months. The prognostic value of the sedimentation rate depends on the fact that it remains rapid in all cases going on to chronicity even though the Addis count may temporarily be normal. Occasionally the sedimentation rate returns to normal at the usual time and the Addis count remains abnormal for several months longer. In such an instance the sedimentation rate is a good prog-

nostic guide, indicating eventual recovery in the face of an abnormal Addis count.

**Urinary findings.** The specific gravity of the urine during the acute phase is usually high even when correction is made for the albumin content. Rarely the ability of the kidney to excrete a concentrated urine is lost early in the disease, and the specific gravity of the urine is low. Retention of nitrogenous wastes is usually associated with this low specific gravity. The volume of urine may be normal, but in most instances it is reduced; in about 5 per cent of cases there is oliguria approximating anuria. It is surprising that these severe states of oliguria are not responsible for extensive generalized edema. Vomiting, which is a striking feature of uremia, probably is a factor limiting water retention. There is no correlation between generalized vasospasm or arterial hypertension and volume of urine or its specific gravity.

Though a definite diagnosis of glomerulonephritis cannot be made in the absence of hematuria, infrequently only a few red blood cells can be detected microscopically at any time in the course of the disease. Gross hematuria occurs in about half of the cases. Freshly passed urine should be examined for both red blood cells and casts, since both may disappear when alkaline or dilute urine is allowed to stand. White blood cells are also found in increased numbers; occasionally so many are present as to suggest pyelonephritis.

The amount of albumin in the urine varies greatly and is not correlated with the severity of the disease. The amount decreases as the renal process heals, and usually parallels the disappearance of red blood cells. In cases going on to latent or chronic stages albuminuria and irregularly recurring hematuria persist; they are more regularly detected by the Addis count than by routine urinalysis. Children with these urinary abnormalities for more than a year after the acute phase should be regarded as having entered the chronic phase, in which the prognosis is grave, though recovery is possible. During convalescence, but not subsequent to recovery, exacerbations are to be expected after an acute respiratory infection (or after tonsillectomy) and are not in themselves a bad prognostic sign.

**Hypertension.** Hypertension is present in about 60 to 70 per cent of the cases. It may appear at any time during the acute phase; systolic pressures may be as high as

200 mm. of mercury, with diastolic pressures of 100 to 120. The rise may be sudden: for example, from a normal level in the morning to high levels by afternoon. The drop may be just as precipitous. In most instances the hypertension is present during the first four or five days of the illness, slowly returning to normal levels by the end of the first week. In some cases, usually those with more extensive renal damage, the hypertension may persist for weeks; in persistent cases it may be permanent.

The mechanism of hypertension in acute glomerulonephritis is considered to be dependent on generalized vasospasm, possibly resulting from renal ischemia, rather than on cerebral edema. Hypertension is associated and directly correlated with cerebral symptoms (hypertensive encephalopathy) and cardiac disturbances.

**Cerebral symptoms.** Cerebral symptoms appear after an acute rise in blood pressure and are probably due to cerebral ischemia resulting from the vasospasm. Symptoms persist during hypertension and consist chiefly in headache, drowsiness, convulsions and vomiting. Restlessness, dimness of vision and diplopia may be associated. The pulse is slow. When the blood pressure is reduced (relaxation of the vasospasm), the cerebral symptoms disappear. There is no correlation between these episodes and the degree of renal impairment or water retention.

Cerebral edema may occur, but certainly it is not the total or the usual explanation for hypertensive encephalopathy. In the majority of cases the cerebrospinal fluid pressure is within normal limits and there is no papilledema. In cases with cerebral edema, papilledema may be present. Furthermore, measures designed to reduce the vasospasm result in a disappearance of the cerebral symptoms, whereas diuretics which induce cerebral dehydration usually fail to control the symptoms. When there is cerebral edema, dehydrating measures may be of aid. Constriction of the retinal arteries is usually the only fundal finding in the acute phase; retinal hemorrhages and exudation are observed only in the chronic phase.

Episodes of hypertensive encephalopathy usually last a day or two and spontaneously end with the fall in blood pressure, although death may occur during the cerebral attack. Recovery under appropriate treatment is usually complete and rapid. It is possible that residual disturbance may occasionally result from prolonged anoxia.

**Cardiac symptoms.** Cardiac involvement is present in about 75 to 80 per cent of the cases. Usually evidence of it is limited to electrocardiographic changes. Signs of cardiac failure are occasionally the presenting symptoms, and the basic disturbance may be detected only by urinalysis or the finding of hypertension. When the hematuria is not marked and other evidences of severe renal damage are lacking, the diagnosis is difficult. Acute glomerulonephritis is second only to rheumatic fever as a cause of acute cardiac failure in children beyond the age of infancy. Hypertension, though not invariably present, is strong evidence in favor of a nephritic origin of cardiac failure. The increased peripheral load incident to the vasospasm apparently overburdens the weakened myocardium, producing failure, and it is also possible that the generalized vasospasm may result in hypoxia of the myocardial cells. Hypervolemia secondary to retention of sodium and water has been suggested as an etiologic factor in the cardiac failure of nephritis. Others believe that the symptoms ascribed to cardiac failure may occur as a result of hypervolemia in the absence of cardiac failure. The pulse rate during the acute phase of the disease tends to be relatively slow; a rapid rate suggests myocardial damage.

The most striking changes in the electrocardiogram are observed in the T wave, consisting chiefly in flattening or inversion in one or more leads, although a transient increased amplitude of the T wave is occasionally observed. Inversion of the T wave occurs late in the cycle and is not infrequently preceded, especially in leads I and II, by a slightly depressed, upward bowed segment. Transient inversion of the T wave occurs as frequently in lead III as in lead I, but cardiac failure is commoner with inversion of the T wave in lead I.

Cardiac signs usually subside rapidly with the fall in blood pressure, and even the child in cardiac failure will show rapid improvement within a day or two. Usually all evidence of cardiac involvement except that of enlargement will disappear within a week to ten days. The enlargement usually disappears more slowly, requiring about six to eight weeks. The systolic apical murmur is usually the last evidence to disappear. Cardiac failure is a cause of death in acute glomerulonephritis and usually occurs early in the disease. Patients who recover have complete restoration of cardiac function.

**Renal function.** Renal function is im-

paired in most patients early in the disease. The glomerular filtration rate is generally reduced to some extent, and it may be greatly reduced. There is lack of correlation with the extent of the reduction and recovery. The fall in urine volume is in part at least related to reduced filtration; there is, however, evidence that tubular reabsorption of water may be an important factor in the early oliguria and later in diuresis. The volume of urine alone cannot be used as a guide to the extent of renal function, for when concentrating capacity is lost, even early in nephritis, there may be a large volume of dilute urine. In most instances, however, the urinary volume may be used as a guide of renal function. If the volume is not sharply reduced (with an adequate intake) and the specific gravity of the urine is within normal limits, there is no serious functional loss. Persistent oliguria which is not due to severe dehydration is an ominous sign and a measure of renal failure. Retention of nonprotein nitrogenous substances, phosphates, sulfates and potassium is related to the fall in glomerular filtration rate.

Renal plasma flow as measured by para-aminohippurate tends to be normal, or even high. Thus the filtration fraction (F.F.) is almost always reduced, further demonstrating that the glomerulus is the focal point of the disease. Tubular excretory capacity as measured by maximal excretion of para-aminohippurate is reduced in about 50 per cent of patients during the acute phase. The loss of concentrating capacity is additional evidence of tubular impairment.

Recovery of renal function is gradual and occurs with clinical recovery, but may be delayed and return to normal only after several months. Loss of edema and disappearance of hypertension usually antedate recovery of renal clearance functions.

**Diagnosis.** In the usual case of acute glomerulonephritis there are no diagnostic difficulties; the coexistence of hematuria, albuminuria and slight edema, in the absence of cardiac failure, establishes the diagnosis. In cases in which cardiac failure occurs early, the symptoms referable to the failing heart may dominate the picture so that the nephritis may initially not be suspected.

Embolic nephritis is characteristically seen during a bacteremia such as that of subacute bacterial endocarditis; it is transient and disappears when the blood stream is free of bacteria.

Transient hematuria during *acute pyelo-*

*nephritis* may be a diagnostic problem. Large numbers of pus cells in comparison with red blood cells and the bacteriuria aid in the differentiation from glomerulonephritis.

It may be impossible initially to differentiate the hematuria, decreased urinary output and occasional azotemia resulting from sulfonamide crystals. The disappearance of the hematuria and other urinary symptoms within a day or two after withdrawal of the drug is strong evidence against glomerulonephritis. A clinical picture indistinguishable from glomerulonephritis is also occasionally seen in sulfonamide intoxication. Other causes of hematuria such as cystitis (p. 1055), scurvy, blood dyscrasias, calculi, trauma, tumors and tuberculosis of the urinary tract may also require differentiation. The urinary findings at times associated with the Schönlein-Henoch syndrome also require differentiation (p. 921).

Extrarenal azotemia and other waste retention resulting from severe states of dehydration should be recognized. The concentrated urine often contains albumin and hyaline casts, which tend to disappear quickly when the child is hydrated.

Febrile and other benign *albuminurias* at times create diagnostic problems. Febrile albuminuria is usually recognized by its transitoriness and association with febrile states. Since the erect posture may occasionally increase albuminuria in subacute or chronic glomerulonephritis and since the urine in orthostatic albuminuria may rarely contain a slightly increased number of red blood cells and casts, differential diagnosis may be difficult.

**Prognosis.** Although the prognosis of acute glomerulonephritis is generally good, it is unpredictable in the individual case. Thus the mild case may progress to the subacute stage, whereas a patient with fulminating symptoms of hypertensive encephalopathy, cardiac failure and/or renal shutdown may recover completely. There is a positive correlation between the severity of the onset and the fatality rate during the acute stage, but none between the severity of the acute stage and the development of chronic nephritis. Mortality rates during the acute phase have varied from 1 to 5 per cent. Since the availability of antibacterial therapy the rates in most clinics have approached the lower figure. The incidence of chronic nephritis is of about the same order, though rates as high as 5 and 10 per cent have been reported.

Second attacks of glomerulonephritis are

extremely rare. Recrudescence of the disease before healing is complete, however, is common in association with fresh respiratory infections or after removal of infected tonsils or teeth.

In mild cases the entire course may extend for only ten to fourteen days. Protracted cases may show urinary changes for a year, and rarely for a longer period, yet the patients still recover completely. The abnormalities of the urine as demonstrated by routine examination usually disappear within six or eight weeks, and the erythrocyte sedimentation rate becomes normal in about three months, the Addis count in about four months. The persistence of urinary changes for more than one year with evidences of progressing renal failure is indicative of a grave prognosis, death usually occurring within five to ten years.

**Treatment. General.** The treatment of nephritis is largely symptomatic, but should be based on recognized physiologic principles. The child should be confined to bed during the acute phase and until urinary findings approach normal. There is increasing evidence that activity out of bed after the first two or three weeks of the disease does not adversely affect the course. Subsequently the child's urine should be closely watched, and he should be guarded against respiratory infection, chilling and overexertion.

During the first few days of the disease the diet should be a liquid one of sweetened fruit juices and milk. As the acute phase subsides the child may be given a soft diet and soon a regular diet. Salt-free diets are not generally prescribed unless edema is excessive, but during the acute phase salt should not be added to the food during cooking or subsequently. The usual practice is to limit the amount of salt to that used in ordinary cooking. There is little evidence that the protein in the diet needs restriction, except perhaps during the height of the acute stage; certainly restriction of the protein intake below the body requirements beyond this time will lead to the consumption of tissue proteins.

Since positive nasopharyngeal cultures for streptococci are often found at the onset of clinical nephritis, full therapeutic doses of penicillin should be given for a week or so.

Surgical procedures should be restricted to those absolutely essential. Abscesses of the middle ear or in other locations should be drained, but tonsillectomy should not be performed during the first two or three months of the disease. If the operation is performed

at a later date, antibiotic therapy should precede and follow it by two or three days in an attempt to prevent bacterial spread. Nephritis of itself is not an indication for tonsillectomy.

**Treatment of special symptoms.** Children with acute glomerulonephritis may be divided into four general groups on the basis of their clinical patterns.

**GROUP I. Patients with (1) normal blood pressure, (2) good urinary output, and (3) normal or only slightly elevated blood urea nitrogen.** With normal blood pressure, hypertensive encephalopathy will not occur, and there is little likelihood of cardiac failure; with good urinary output and a normal blood urea nitrogen level, acidosis and uremia will not occur. Thus in group I none of the severe complications should arise, and these patients require only general treatment. They should be closely watched, however, for a possible change in their status.

**GROUP II. Patients with (1) elevated blood pressure, (2) good urinary output, and (3) normal blood urea nitrogen.** The elevated blood pressure, indicative of vasospasm, may result in hypertensive encephalopathy and in cardiac failure. For these reasons attempts should be made to lower the blood pressure when the diastolic pressure is over 95 mm. or the systolic pressure is over 140 mm.

Magnesium sulfate has been the most effective and widely used hypotensive agent for the control of hypertension in nephritis. It is toxic and can produce severe respiratory depression and in large doses has a direct action on cardiac muscle. Toxic manifestations can be avoided by appropriate dosage and can be counteracted by the intravenous administration of 5 to 10 cc. of a 10 per cent solution of calcium gluconate or a 5 per cent solution of calcium chloride. In the presence of oliguria, magnesium sulfate should be given with extreme caution (see group IV). A 50 per cent solution of magnesium sulfate in a dose of 0.2 cc. per kilogram of body weight injected intramuscularly will usually lower the blood pressure within one to two hours by relaxation of the vasospasm. In some instances this dose will have to be repeated several times at intervals of four hours to keep the pressure at a satisfactory level. In about half of the cases there is no striking effect of the magnesium sulfate; there seems to be some correlation between the amount of urine and the reduction in blood pressure, the drug being less effective

in the presence of a large urinary output, so that effective blood concentrations are not obtained. In these latter instances larger doses of the drug are needed to produce the desired effect. When there are severe manifestations of encephalopathy such as diplopia, coma and convulsions, the drug can be given intravenously as a 3 per cent solution of the hydrated salt. The total dose of 150 to 200 mg. per kilogram of body weight should be given in the course of one hour, half of it in the first fifteen to twenty minutes. The blood pressure and the respirations should be observed constantly during this time.

Recently the combination of reserpine and hydralazine hydrochloride (Apresoline) has been found to be effective. Reserpine is mildly hypotensive and also allays anxiety; Apresoline is a more potent hypotensive agent. Reserpine is given in a dose of 0.07 mg. per kilogram simultaneously with hydralazine, 0.1 mg. per kilogram intramuscularly. The effect of this combined therapy is elicited within one-half hour and may persist for twelve or more hours; a single administration is adequate in the majority of instances, but may need to be repeated after twelve hours. The dose of reserpine alone often relieves mild hypertension, or the drug may be given orally subsequent to the initial intramuscular injection in conjunction with hydralazine in amounts of 0.02 to 0.03 mg. per kilogram per day in divided doses.

If hypertensive encephalopathy has developed, the reduction of the blood pressure will usually relieve the symptoms. Sedation may be necessary, however, for the control of convulsions, or, in the presence of associated cerebral edema, lumbar puncture may stop them. Oxygen therapy is also indicated.

When cardiac failure has developed, treatment aimed at improving the myocardial status is indicated. Sedation with opiates is perhaps the most helpful measure. Digitalization is effective, and relatively large doses are tolerated. Total doses of 30 to 40 mg. per kilogram of body weight of the powdered leaf are effective. One sixth of the total dose is given orally as a test dose. Then, if there are no untoward symptoms, a similar dose is administered every four hours until the total dose has been given. It is rarely necessary to give a maintenance dose. A more rapid form of digitalization is effective with a single oral dose of digitoxin or some similar product, 0.035 mg. per kilogram of body weight. Oxygen administration in a tent is

beneficial. Phlebotomy is of doubtful value, and dehydrating agents are not without danger. Cardiac failure has been observed after intravenous injection of 50 per cent sucrose; the sudden increase of blood volume induced by this hydropic agent probably accounts for the effect on the heart. When the blood pressure is reduced, the cardiac symptoms rapidly disappear, and bed rest is the only therapy needed for the heart. The cardiac status, however, should be followed by serial electrocardiograms and roentgenograms.

In the presence of hypertension, restriction of fluid intake is advisable in order that enlarging blood volume does not further hamper cardiac action. In these circumstances the fluid intake is limited to an amount equal to insensible water loss and urinary output; for an average seven-year-old child about 800 to 900 ml. a day. If the urinary volume is large, drastic restriction of fluids is not necessary. When the blood pressure is within normal limits, the management is that described under group I.

**GROUP III.** *Patients with (1) normal blood pressure, (2) small urinary output, and (3) elevated blood urea nitrogen.* When the urinary excretion is decreased, there is a tendency toward acidosis, uremia and edema. In this group of patients it would be desirable to increase the urinary output so that the waste products of metabolism could be excreted. There are no therapeutic measures, including the various diuretics, which will increase glomerular filtration.

The daily water intake can be determined on the basis of the volume of urine excreted on the previous day and the estimated insensible water loss (approximately 700 cc. per square meter). One should make certain that enough water is taken to prevent dehydration and to provide the kidneys with sufficient fluid for their maximal excretory capacity of the moment. When there is uremic vomiting, fluids should be given intravenously or subcutaneously to restore body water and electrolytes and so prevent dehydration and acidosis which further depress renal function. *Potassium-containing solutions should be avoided when there is oliguria or anuria.* Sodium lactate is used to correct acidosis if it is severe, and glucose in a 10 per cent solution is given intravenously to prevent ketosis and further tissue breakdown. Owing to the danger of fluid retention, electrolyte-containing solutions are not given

except when the serum levels of sodium and chloride are greatly reduced. When there is severe nitrogenous retention, dietary protein is eliminated. Cation exchange resins may be used when there is potassium retention, as reflected by an elevated serum level and by electrocardiographic changes; for example, 100 ml. of a 10 per cent solution of ammonium carboxylic exchange resin may be instilled rectally at intervals of four hours as a retention enema. If the serum phosphorus rises to high levels, calcium gluconate is administered orally to lessen the possibility of tetany. Thorazine may be helpful in the control of vomiting.

The so-called artificial kidney and peritoneal lavage have been used during periods of prolonged anuria; the technical aspects of such therapy have been improved in recent years, but it is justified only in adequately selected patients and then by experienced clinicians. Exchange transfusions have also been used. Decapsulation of the kidney or denervation of it and roentgen ray treatment over the renal area are not recommended. Anuria lasting several days is compatible with life if the biochemical and water status of the body is properly maintained; therefore these more drastic measures should not be used unless the anuria persists for five to seven days. When diuresis is established, the management is similar to that described under group I.

**GROUP IV.** *Patients with (1) elevated blood pressure, (2) small urinary output, and (3) elevated blood urea nitrogen.* This group is the most difficult to manage because of the potential danger of all three major complications: cardiac failure, hypertensive encephalopathy and uremia. Since little can be done to improve kidney excretion and since diuresis occurs as quickly with water restriction as with the forcing of fluids, water should be restricted.

A hypotensive agent should be administered to reduce the blood pressure and so lessen the possibility of cerebral and cardiac complications. In view of the small urinary output in these patients, magnesium sulfate should be given with extreme caution, the initial dose being only one half the doses listed above. In the presence of severe oliguria it is safer to use the combination of reserpine and hydralazine or reserpine alone (see group II). When the blood pressure has been reduced to a satisfactory level, the management is similar to that described under group III. The blood pressure should be measured at

least three times a day, since it may again become suddenly elevated.

### **NEPHRITIS IN SCHÖNLEIN-HENOCH SYNDROME**

(ANAPHYLACTIC PURPURA) (See also p. 920)

The renal manifestations of this disease, generally believed to result from a state of hypersensitivity, are common and may be serious. In the early stages the lesions resemble those of lupus erythematosus more closely than acute glomerulonephritis, but later they more clearly resemble glomerulonephritis. The renal manifestations may be minimal and be manifest as microscopic hematuria, or they may be severe and resemble classic glomerulonephritis. A striking feature of the nephritis is recurrence of gross hematuria with clearing of the urine in the intervals. The recurrence of hematuria may or may not be associated with recurrent purpura. As in glomerulonephritis, acute renal failure and severe hypertension with encephalopathy may occur. This form of nephritis is more likely to be persistent than is the usual acute glomerulonephritis.

### **IRRADIATION NEPHRITIS**

Acute and progressive glomerulonephritis may follow roentgen therapy of the abdominal area. Usually there is an interval of several months between irradiation and the manifestations of nephritis. The prognosis is generally bad.

### **FAMILIAL HEREDITARY NEPHROPATHY AND DEAFNESS**

This syndrome is characterized by hematuria, cylindruria and albuminuria. The hematuria may be demonstrable only microscopically, or the urine may be grossly bloody. Remissions are common, and exacerbations may be associated with infections. The condition is hereditary. It is more severe and progressive in the male. In the female the disease is often compatible with a normal life span. Nerve deafness has been reported only in patients with renal involvement and apparently is present in almost all affected males. It is not present at birth, but is usually progressive when it becomes manifest. Congenital abnormalities of the eyes also occur in these families.

Nerve deafness is usually the first complaint. Renal function is usually maintained for some time, but occasionally hypertension

and renal dysfunction occur early. There is no specific treatment.

### CHRONIC GLOMERULONEPHRITIS

Whereas acute glomerulonephritis is much more common in children than in adults, the reverse is true for chronic nephritis. On the other hand, acute glomerulonephritis is more frequently followed by chronic nephritis in adults than it is in children (perhaps not more than 1 or 2 per cent). Most often chronic glomerulonephritis in children has an insidious onset without a known origin. The higher incidence of chronic glomerulonephritis in adults than in children is not dependent on progression of the disease from an acute episode in early childhood.

**Pathology.** The kidney is small and contracted. The capsule is adherent, and the surface of the kidney is finely granular as a result of disappearance of many nephrons and hypertrophy of others. Histologically, many of the glomeruli are hyalinized or have completely disappeared. The remaining functional glomeruli reveal varying degrees of endothelial and epithelial proliferation and hyalinization. Many tubules are atrophic or have disappeared; the remaining ones are often enlarged and cystic. Extensive scar tissue replaces the areas in which nephrons have disappeared, where there is often a focal and diffuse infiltrate of lymphocytes. The arteries and the arterioles associated with damaged or destroyed nephrons reveal extensive degenerative changes, with hyalinization of the arteriolar walls and intimal thickening of the arteries.

**Clinical Manifestations.** The chronic form of glomerulonephritis is characterized by repeated acute exacerbations for a number of years. These are often preceded by acute infections in the upper respiratory tract with the beta hemolytic *Streptococcus*. With each acute flare-up there is a further reduction of renal function, which usually does not return to its previous level, and eventually there is terminal uremia and death. It is remarkable how well the child may look and act when renal function has been reduced almost to the vanishing point. Rapid growth which takes place about the time of puberty often is the final strain which disrupts the renal effort and is responsible for death.

Edema is not a striking feature of the so-called dry type of chronic nephritis, although edema may be present more or less constantly about the eyes and ankles. In the nephrotic

phase of chronic glomerulonephritis, edema may be as striking as in the nephrotic syndrome, and there may also be a reversal of the albumin-globulin ratio in the serum and a mild elevation of the cholesterol. Thus differentiation may be difficult. Not infrequently during this phase of chronic glomerulonephritis there is a decrease in retention of nonprotein nitrogen and in the hypertension; hematuria may be inconstant. When renal function is notably impaired, polyuria and low, fixed specific gravity of the urine become evident, and edema often disappears. The patient may even become dehydrated and salt-depleted; when there is cardiac failure associated with hypertension, the edema may return.

The urinary changes are extremely variable. Albuminuria is constant, but varies in amount. In the final stages, owing to the dilution of the urine, there may be only traces of albumin; in the nephrotic phase large amounts are present. Hematuria also varies in degree, blood being present usually in only microscopic amounts and at times being entirely absent. There may be gross hematuria during an acute exacerbation. Casts are found irregularly in the ordinary examination, but by the Addis technique they are consistently increased in number. The urea and other clearance tests show gradual but progressive loss of function, which is also evidenced by the low, fixed specific gravity of the urine.

There are periods when improvement seems to occur, but the trend is definitely downward. Nitrogen retention is constant; anemia is progressive and may be severe. Associated with sudden rises in blood pressure, there may be episodes of hypertensive encephalopathy and cardiac failure; death may occur at such times. For most of the course the child may feel well enough to be, up and moderately active, pallor and undernutrition being the only presenting symptoms. As the terminal stage is reached he becomes bed-ridden, loses his appetite, complains of headaches and muscular cramps and may have convulsions. Diarrhea and vomiting occur. Arteriolar changes appear in the retinal vessels at this stage, resulting in hemorrhages and exudation, and edema of the optic disks. These patients are highly susceptible to infections; eventually they become uremic with coma preceding death. Elevation of the blood potassium level may produce severe changes in the heart which are demonstrable by electrocardiography.

So-called renal rickets with osseous changes is not likely to occur in this form of chronic renal disease, yet stunting of growth, retention of phosphate, low blood calcium levels and acidosis may be observed in association with tetany.

**Differential Diagnosis.** The differential diagnosis from *congenital polycystic* and *hypoplastic kidneys* may be difficult without urographic studies. *Periarteritis nodosa*, *lupus erythematosus* and so-called vascular nephritis (p. 1049) may simulate chronic glomerulonephritis, as may the terminal phase of pyelonephritis.

**Prognosis.** The decrease in renal function may be slow, but the downward course is inevitable; in an occasional case progression downward is rapid, and death occurs from uremia within a few months. More often death takes place within five to ten years.

**Treatment.** Though the downward course of the disease cannot be significantly altered by therapy, many children can have their lives prolonged and made happier by appropriate management. The child should be permitted to lead as normal a life as is compatible with his abilities. Care should be given to the establishment of a healthy mental attitude toward his limitations; it is also important that the parents maintain as bright an attitude as possible in the face of the impending catastrophe.

The child should be guarded against acute respiratory infections, and nutritional needs in all categories should be fully met. The minimal protein requirements of a normal child of the same age and weight should be permitted. Any severe deficiency in the serum protein should be corrected with injections of plasma. Salt restriction is indicated only during a nephrotic phase or in the presence of edema due to congestive cardiac failure. Hypochloremia and hyponatremia during nephritis may be factors further depressing renal function. During episodes of acute hypertension with impending cardiac failure and hypertensive encephalopathy, magnesium sulfate or reserpine with or without hydralazine hydrochloride, in doses as described under the acute form of the disease, is indicated. Severe anemia requires transfusions for its correction. Removal to a warm, dry climate, especially during the "respiratory season," may reduce the acute exacerbations and thus tend to retard the downward progression. When acute infections develop, antibiotic therapy is indicated. (See Treatment of Uremia, page 1051.)

## NEPHROTIC SYNDROME

### (NEPHROSIS)

The nephrotic syndrome is characterized by excessive edema, proteinuria, hypoalbuminemia, hypercholesterolemia and a course lasting many months or years. The frequency of nephrosis is not known; an incidence of about seven cases per 100,000 population under the age of five years has been estimated. In so-called lipid nephrosis, hematuria, hypertension and azotemia may be minimal and transient. Many children who are initially thought to have lipid nephrosis are subsequently found to have chronic glomerulonephritis.

**Etiology.** The etiology of nephrosis is not known. Except for relatively rare instances of a nephrotic clinical pattern, associated with specific diseases such as syphilis, amyloid disease, thrombosis of the renal vein, disseminated lupus erythematosus, poison oak dermatitis, bee sting and toxic reactions to certain metals and drugs (e.g., mercury and Tridione), the clinical condition known as the nephrotic syndrome consists of disturbances which are classified in two categories as lipid nephrosis and the nephrotic phase of subacute or chronic glomerulonephritis. It is not definite whether these two subdivisions are variants of the same pathologic process or are separate entities. If the former, then it would have to be concluded that those children who have unquestioned evidences of progressive glomerulonephritis have irreversible changes which would lead to uremia and a fatal termination; whereas those whose disease at a given moment could be classified as nephrosis have the potential for either complete recovery or development of irreversible changes.

In most instances it is not possible to relate the onset of nephrosis to some other disturbance. Exacerbations, however, in the nephrotic syndrome often follow acute infections. A clinical pattern in rats which simulates the transition from lipid nephrosis to chronic glomerulonephritis was produced by Heymann and Lund by injection of an anti-kidney serum. Initially there is a degenerative phase, characterized clinically by the nephrotic syndrome. This phase is followed by fibrous proliferation in the glomeruli, manifest clinically by hypertension and uremia. These observations in conjunction with those in children of a decrease in blood complement during active phases of the disease and of an increase during remission suggest the

possibility of an antigen-antibody reaction as an etiologic factor.

Nephrosis is primarily a disease of childhood, the average age at onset being about two and a half years; it is uncommon under one year of age. It is more common in boys than in girls. On occasion nephrosis may follow a familial pattern, when the onset may be earlier, even in the newborn period, and the course more severe.

**Pathology.** The kidneys are enlarged and yellowish, with smooth external surfaces and thickening of the cortices; streaks of bright yellow lipid material may be present in the cortex. The tubules are dilated, and the cells show varying degrees of hyaline granular degeneration; many of them contain doubly refractile lipid droplets.

Much of the controversy about this disease as a distinct entity is related to whether glomerular changes occur early in the disease. In so-called lipid nephrosis Ehrlich and others, using a special stain, described consistent changes in the intercapillary basement membrane of the glomeruli with thickening and so-called fibrinoid degeneration. These observations support those of Bell, who described the essential lesion as a thickening of the capillary basement membranes of the glomeruli which renders them permeable to protein. This thickening may progress to such a degree as to bring about closure of the capillaries and renal insufficiency.

The clinical features of the nephrotic syndrome may be produced not only by thickening of the capillary basement membranes, but also by other glomerular lesions which permit excessive loss of plasma protein in the urine, e.g., proliferative glomerulonephritis or amyloid disease of the kidneys. Vernier, using electron microscopy, has consistently demonstrated distorted epithelial foot processes along the surface of the basement membrane in children with the nephrotic syndrome. This alteration has not been present except in association with the nephrotic syndrome. Cellular proliferation similar to that of glomerulonephritis has also been found early in the disease in needle biopsy material by Galán and Masó.

No extrarenal lesions have been discovered.

The pathogenesis of edema in nephrosis is not entirely clear. The low intravascular osmotic pressure secondary to hypoproteinemia is an important factor. The loss of edema fluid when the serum albumin is still at a low level, however, suggests that some additional factor must operate in control of the

edema. Luetscher demonstrated an increase in aldosterone, a potent sodium-retaining adrenal hormone, in the urine of nephrotic patients during the edema phase and a return of it to normal levels after diuresis. During diuresis the excretion of sodium and chloride in the urine increases and may continue for some time after weight loss has ceased. The lowered glomerular filtration rate presumably is also a factor in water retention. However, since higher filtration rates occur early in the disease in many patients, the lowered filtration rate would not seem to play a prominent role.

It is generally believed that the reduction in serum albumin is due primarily to urinary loss. Recent studies of Gitlin, however, suggest that there may be an associated increased catabolism of serum albumin, which at times may be a significant cause of the low serum level.

**Clinical Manifestations.** Edema is the usual presenting symptom. At the onset the child rarely appears ill, except when an acute infection precipitates the attack. The development of severe generalized edema may be abrupt, but more often the edema during the initial stage of the disease is slight and inconstant, appearing only about the eyes and ankles. Finally, edema fluid accumulates in great quantity; in some instances the patient almost doubles his true weight. This phase may last several weeks to months. Characteristically, the course of nephrosis consists in recurrent accumulations of edema fluid after partial or complete remissions resulting from spontaneously induced diuresis. The urinary output varies inversely with the edema. As the disease becomes well established, pallor develops, but may not be related to any significant degree of anemia. The appetite fails, lassitude and irritability generally develop, and malnutrition may become severe. During edema the loss in body tissue is masked, only to become glaringly apparent when the edema is lost. The edema may become so extensive that it seems as if the skin would rupture; at such times ascites is usually marked, and there may be a bilateral hydrothorax. Intense edema of the scrotum is characteristic. The edema in the peripheral tissues is dependent and shifts with change in posture. In well established cases the peripheral edema may be minimal, with large accumulations of ascitic fluid. Diarrhea and vomiting are not uncommon during the periods of generalized edema; edema of the intestinal wall may be the factor in the intestinal disturbance. Under such circum-

FIG. 313. Nephrosis in a boy 4 years of age. Edema of insidious origin started several months before admission without any preceding infection and varied from time to time. The urine contained large amounts of albumin and some hyaline casts, but never blood. There was no increase in blood pressure, and no azotemia. Total blood protein, 3.86 per 100 ml.; albumin, 1.79; globulin, 2.07; cholesterol, 300 mg.

stances there may also be a flat glucose tolerance curve which returns to normal in the edema-free interval. Interference with digestion of other food substances may also occur.

Most of the physical characteristics of the disease (respiratory distress, abdominal distention, umbilical and inguinal hernias, rectal prolapse and decreased ambulation) are related to the extent of the edema. The liver is often moderately enlarged. The blood pressure is usually normal; transient elevation may occur early. Persistent hypertension accompanies advanced renal insufficiency. In the absence of infection there is no fever; in fact, there may be no fever even with a severe infection.

Children with nephrosis are unusually susceptible to infection. Repeated acute upper respiratory tract infections are often engrafted on what appears to be a chronic one. The *Pneumococcus* is a common offending organism, but infection with the hemolytic *Streptococcus* and other pathogens is not uncommon. The clouding of the paranasal sinuses as seen on the roentgenogram is probably more dependent on the edema of the mucous membrane than on the existence of bacterial infection. On rare occasions there has been complete recovery from nephrosis after an acute bacterial infection. Remissions following measles are common.

Erysipeloid lesions which consist of red, blotchy, tender patches occasionally occur on various parts of the body, accompanied by fever and other signs of acute illness. The urinary volume may sharply decrease at this time, and the edema becomes more extensive. Such an episode has been called a crisis. Although many explanations have been given to account for this sudden change in the clinical picture, infection would seem to be

a probable cause. A fall in the blood amino acid level accompanies the attack.

Signs of glomerulonephritis with hematuria, azotemia and hypertension eventually develop in many children who appeared to have had a lipoid nephrosis at the onset. Rarely a nephrotic episode is precipitated by clinical evidences of acute glomerulonephritis. With progression of the disease there is a tendency to persistence of edema with minor fluctuations, and the urine volume tends to be small. In the end stages the patient may become relatively free of edema. Cardiac failure may occur and in the presence of extensive edema can be misinterpreted.

Xanthomatous lesions may be associated with high blood cholesterol levels (p. 1002). The basal metabolic rate is usually within the normal range if correction is made for the overweight due to the edema fluid.

The most important laboratory finding is proteinuria with an albumin-globulin ratio between 5:1 and 1:1. Heymann noted that the ratio was less than 1:1 in a group of patients whose disease was progressive. The total daily urinary output of protein is commonly as high as 10 to 15 gm., and may be higher. During the accumulation of edema fluid the urinary volume is reduced, and the specific gravity of the urine is high. Diuresis of large amounts of urine accompanies disappearance of the edema. Hyaline, granular and cellular casts are found in large numbers, and many contain doubly refractile lipoid bodies. These lipoid bodies are also found free in the urine. There may be some increase in leukocytes. Neither the presence nor the absence of a small number of red blood cells early in the course of the disease seems to have prognostic significance. The development of persistent hematuria, however, is a serious prognostic omen. As with hematuria,

there may be transient and moderate nitrogen retention which does not necessarily indicate progressive renal failure. There is little tendency toward acidosis in the early stage of the disease. In the "non-nephritic" phase renal function tests reveal normal and even elevated capacities. In the "nephritic" phase there is progressively decreasing function as measured by the various tests.

The characteristic changes in the blood are a lowering of the serum albumin sufficient to produce a reversal of the albumin-globulin ratio and an increase in the blood lipids, particularly in the cholesterol fraction, with levels of 300 to 1800 mg. per 100 ml. The ratio of free to esterified cholesterol is unaffected. There is an increase in the ratio of total cholesterol to phospholipids, the greatest increase occurring in the fraction of cholesterol bound to beta-lipoprotein. The major reduction in serum protein is in the albumin fraction; edema develops at levels of about 2.5 gm. per 100 ml. In some cases the albumin is reduced below 1 gm. per 100 ml. These low levels may persist even after edema has entirely disappeared, and then slowly rise as the disease process subsides. The total globulin fraction may be normal or slightly elevated; the gamma globulin fraction is reduced, and the alpha and beta fractions may be increased. The fibrinogen is often increased. The plasma volume is reduced in most cases, but rises during diuresis.

Slight or even severe secondary anemia may be present, the latter usually when clinical glomerulonephritis coexists. The erythrocyte sedimentation rate is rapid. The serum calcium is frequently reduced with chronic glomerular disease; tetany is an occasional complication. Glycosuria occasionally occurs without a coexisting hyperglycemia. Woolf and Giles found two patterns of amino-aciduria: one suggestive of a defect in renal tubular reabsorption and the other of a disturbance primarily in amino acid metabolism. The prognosis was worse with the first pattern.

The ascitic fluid is nearly always opalescent, appearing like slightly soapy water. The protein content averages about 0.2 per cent.

**Prognosis.** The course of nephrosis is variable, but in general is characterized by recurrent episodes of edema of varying length. Though the untreated child is seldom completely free of edema during the active phase of the disease, he may appear to be so after rapid loss of large quantities of edema fluid. Even in cases which go on to recovery, albu-

minuria may persist for weeks or months, and the return of the other chemical changes to normal may be slow. The cholesterol is usually the last blood constituent to return to normal; it may remain elevated for months. The erythrocyte sedimentation rate usually remains rapid as long as the disease exists.

Since mild hematuria and azotemia may be present early in the course of lipoid nephrosis and then disappear, it is not possible to prognosticate the outcome of the individual case early; the patient may eventually recover, or progress to ultimate renal failure. The speed of progression cannot be foretold, owing to the great variations in the clinical course of the disease. Serial renal biopsies may prove to be of some aid in gauging prognosis.

Reports of the incidence of complete recovery from nephrosis differ widely. Antibacterial therapy has greatly reduced the death rate from infection, but seems to have had little effect on the incidence of progressive glomerulonephritis. There is an impression that a higher percentage of children with nephrosis without evidences of loss of renal function are recovering completely than was so before the availability of effective antibacterial agents. The possibility is suggested that control of intercurrent bacterial infections is permitting a large number of children to survive until the nephrosis spontaneously disappears.

The results of therapy with corticotropin or one of the corticosteroids at present appear to be favorable and to justify use of such therapy for a relatively long time. It must be recognized, however, that adequate evaluation of the relative benefits and potential dangers of continued therapy is not possible at this time. There is consensus that short-range therapy directed simply at control of edema has not affected the course of the disease. By contrast, longer-range therapy appears to have reduced the mortality to some extent; whether this merely represents a prolongation of life, and, if so, of what extent, it is not possible to say. Certainly such therapy has enabled many nephrotic children to lead active lives, approaching that of the average child, whereas otherwise their activity would have been greatly restricted. It must be recognized that such therapy is not without risk (see p. 1181).

Unfortunately, adequate data of case fatality rates are not available for comparative purposes; data are currently being collected on a cooperative basis in a number of clinics. Subsequent to the availability of effective

antibacterial agents and prior to the availability of hormonal therapy, recovery rates have been estimated at 30 to 50 per cent. Hormonal therapy apparently has not affected the course of the disease after the appearance of definite evidences of progressive renal failure.

**Treatment.** Treatment aims at prevention and control of acute infections, establishment of good nutrition, readjustment of the disturbed metabolic processes, control of edema, and establishment of good mental hygiene. In view of the chronic and recurrent feature of the disease, which causes great discouragement to both child and parents, time must be spent in acquainting the parents with the nature of the illness and the rationale of the therapy. The child should be kept in bed only during periods of severe edema or when other constitutional symptoms are present. Otherwise the child should be out of bed and active, but should have adequate rest and be reasonably guarded against exposure to infection. Prophylactic administration of sulfadiazine or penicillin in a fashion similar to that in rheumatic fever (see p. 910) is recommended. Acute infections should be treated promptly with appropriate antibacterial therapy. Careful nursing attention is needed to protect the edematous skin from injury and subsequent secondary infection. The flagging appetite should be tempted with attractively prepared food which is easily handled by the disturbed gastrointestinal tract. The diet should be well balanced and contain an adequate amount of protein to compensate for that lost in the urine. When possible, these patients should be treated at home and brought to the hospital only for special therapeutic measures.

Many methods have been used in an attempt to induce diuresis. The administration of corticotropin or one of the corticosteroids has provided the only practical effective means. Attempts to raise serum protein levels by administration of blood plasma have not been very successful. However, plasma, concentrated salt-poor albumin or other plasma substitutes, such as 12 per cent dextran solution, may induce diuresis temporarily. Care should be taken to prevent rapid expansion of plasma volume. Diuretics are most often ineffective in inducing diuresis, and are rarely used now that steroid therapy is available. Death has occurred immediately after intravenous injection of mercury.

Depletion of body sodium by the use of cation exchange resins has not been widely

used in children. Salt-poor diets have been tried in attempts to lower the body's store of sodium, but they are not well accepted by the child, and his nutrition suffers. In the presence of excessive edema it is advisable to reduce the salt intake for short periods. Prolonged dietary salt restriction may lead to hyponatremia, particularly during periods of diarrhea or diuresis.

Hormonal therapy with corticotropin or one of the corticosteroids is now widely used, and there is reasonable consensus that all nephrotic children, except those in renal failure, are entitled to a trial with such therapy. Short-term therapy designed to stimulate diuresis and hence reduction of edema has now been largely supplanted by more prolonged therapy. Corticotropin is infrequently used, since it must be given parenterally; prednisone is perhaps the most widely used of the corticosteroids.

Therapy with a corticosteroid is less effective when started after months of persistent clinical disease and is preferably begun when the disease is first recognized. Steroid therapy should be delayed until any existing infection is brought under control and any serious electrolyte imbalance is corrected. Severe hypertension is a contraindication to corticosteroid therapy and should be controlled before steroids are given. Hematuria, minimal azotemia and minimal hypertension are not contraindications. However, complete clinical and biochemical remissions are less likely in patients with evidences of advanced glomerular damage, and complications of steroid therapy are more frequent.

The dose of cortisone is not sharply defined: amounts ranging from 8 to 11 mg. per kilogram per day (350 to 500 mg. per square meter per day) are used for oral administration in divided doses; prednisone, which has certain advantages, is prescribed in daily doses equal to one fourth to one fifth of those of cortisone. The calculated dose of the steroid is given daily for about four weeks, by which time there are usually clinical remission and disappearance of proteinuria. Diuresis usually occurs within seven to fourteen days, but may be considerably delayed. Albuminuria usually disappears within one to two weeks of continuous treatment, but it may also persist longer. If there is no clinical response after a four-week course of steroid therapy, it may be discontinued for one to two weeks, and then repeated. However, prolonging the initial course of therapy beyond four weeks may result in remission.

If no serious complication arises, steroid therapy may be continued for two months or more. When there is failure to respond to the recommended doses of steroids, increasing the dose is usually not helpful.

After the initial remission various programs of steroid therapy have been used in an attempt to maintain the patient free of symptoms. Some have recommended that steroids be withdrawn until significant proteinuria recurs and then started again. This plan has been largely supplanted by programs of more or less continued therapy. In our clinic "maintenance" therapy is begun immediately after the initial four weeks of continuous therapy, provided remission has occurred. The same daily dose of the steroid is given on the first three days of each week, with none on the remaining four days. This program is continued for six to twelve months. If a recurrence develops during this period of intermittent therapy or after its completion, a full course of continuous therapy for twenty-eight days is again instituted to produce a remission, after which the intermittent therapy is again given.

Significant elevation of the blood pressure is an indication for withdrawal of hormonal therapy if the hypertension cannot be controlled, since severe hypertensive encephalopathy may result. Owing to the increased susceptibility to and the masking of signs of infection during hormonal therapy, prophylactic antibiotic therapy should be given throughout the course of therapy. Occasionally excessive water and salt retention results in severe anasarca necessitating temporary withdrawal of hormonal therapy. The alterations in chemical composition of the body fluids which accompany hormonal therapy necessitate frequent analysis of the plasma electrolytes for guidance of the therapy. The daily administration of 2 to 4 gm. of potassium citrate or chloride daily is indicated as long as there is adequate urinary output. Sodium chloride is not added to the diet in cooking or subsequently. Signs of Cushing's disease usually do not appear during short courses of therapy. Any tendency to "moon facies" disappears after reduction or withdrawal of therapy. Transient glycosuria may occur.

Nitrogen mustard has also been used with some success in inducing remissions similar to those produced by hormonal therapy. Induced or naturally contracted measles may also result in remissions. A similar remission

is occasionally seen in association with other infectious diseases.

In patients with large ascitic collections peritoneal drainage may be necessary to relieve respiratory and cardiac distress or disturbances from pressure on the gastrointestinal tract. Such drainage is rarely required for patients receiving corticosteroid therapy.

When renal failure is advanced, the fluid intake should vary with the urine volume and the capacity for renal concentration. In the face of oliguria excessive fluid intake may lead to pulmonary edema and cardiac failure, and during polyuria restricted fluid intake may lead to dehydration with further impaired renal function. With development of acidosis secondary to tubular deficiency oral alkali therapy may be necessary. Since hypocalcemia may exist, care should be exercised in correcting the acidosis in order not to precipitate active tetany. To decrease the tendency toward potassium intoxication during advanced renal failure, the diet should be low in protein and high in carbohydrate, but care should be taken not to deplete the body stores of protein or potassium. Electrocardiographic tracings are valuable in detecting early evidence of potassium intoxication. Phosphorus retention may be reduced by feeding aluminum hydroxide to decrease intestinal absorption; calcium should be given orally when there is hypocalcemia.

Good pediatric care for the child in his family group is of the greatest importance.

## VASCULAR NEPHRITIS

### (ARTERIOLAR NEPHROSCLEROSIS)

This condition, common in adults, is rare in children, but may occur even in infants. There is arteriolosclerosis of the entire vascular system. The media of small arterioles are at first thickened and then become hyalinized, decreasing the diameter of the lumen. The renal vascular changes are similar to those in chronic pyelonephritis associated with long-standing hypertension. In the latter instance there may also be changes in the arterioles of other organs, but they are minimal. The differential diagnosis between so-called essential arteriolosclerosis and severe hypertension secondary to pyelonephritis may be difficult and, at times, impossible except at autopsy.

Renal impairment and hypertension are regularly present. Death usually results from cardiac failure, cerebral hemorrhage or

uremia. Large volumes of urine with a fixed, low specific gravity are excreted, owing to faulty tubular reabsorption. There is slight to moderate albuminuria. Rarely, massive hematuria occurs, but hemorrhages from other organs, as from the gastrointestinal tract, may occur.

Cerebral symptoms often dominate the picture with headaches, drowsiness and episodes of hypertensive encephalopathy, or signs of cerebral hemorrhage. Retinal changes are common and consist in constriction of the arterioles, hemorrhages, exudation, and choking of the disks. Vomiting and abdominal pain may be prominent features. The course of the disease is usually rapidly downward.

### RENAL FAILURE

#### (UREMIA, LOWER NEPHRON NEPHROSIS AND TUBULAR NECROSIS)

Renal failure as a complication of glomerulonephritis, pyelonephritis, polycystic disease and nephrosis has been discussed under the respective headings of these diseases. It may complicate a variety of other conditions such as generalized infections, ingestion of toxins and poisons, circulatory diseases of the kidney, such as bilateral cortical necrosis, renal vein thrombosis and infarction of the kidney, acute liver disease and a variety of congenital renal anomalies involving both structural and functional systems. Functional disruption may involve the entire nephron or predominate in or be limited to glomerular or tubular dysfunction. The terms "lower nephron nephrosis" and "tubular necrosis" have been ascribed to conditions characterized by evidences of severe tubular dysfunction. The pathologic lesion is not limited to any single portion of the nephron and may involve both glomerulus and tubule and may be found in such conditions as traumatic and postoperative shock, the crush syndrome, sulfonamide intoxication, mismatched blood transfusions, various hemolytic anemias (e.g., blackwater fever of falciparum malaria), heat stroke, thermal burns and many other conditions. Lucké believed that vasoconstriction with decreased renal blood flow (anoxia) is the basis for the renal lesion.

**Clinical Manifestations.** The clinical manifestations vary with the primary disease and with the renal functional derangement. Depression of glomerular function is reflected in nitrogenous and other waste retention, often with an elevation of the plasma phosphorus and potassium levels

and acidosis. The urine usually contains protein and casts; with renal vascular thromboses or infarctions there may be hematuria. Urine flow may be decreased, and edema may result if fluids are excessively administered. With depression of tubular function there may be a loss of renal concentrating capacity with passage of a large amount of urine with a low specific gravity. Loss of acid-base-regulating mechanisms of the tubules may result in passage of an alkaline urine (pH above 6.5) in the presence of acidosis. Renal glycosuria may result from some specific defect in tubular function, and a variety of other defects are described, such as deficiency in bicarbonate reabsorption, excretion of amino acids and other organic acids and deficiency of phosphate reabsorption. In the acute phase of glomerular tubular imbalance a high percentage of the glomerular filtrate may be reabsorbed, leading to severe oliguria. In some instances of acute renal failure with acidosis the symptoms may resemble those of pneumonia. In less advanced cases the presenting and only symptom may be retardation of growth, reflected in both weight and height. Anemia is a common feature, due largely to depression of bone marrow activity, but a hemolytic component has also been demonstrated, and the anemia may require transfusion. Gastrointestinal symptoms may predominate, with vomiting and, less commonly, diarrhea. Dehydration may be severe. In advanced and prolonged cases the serum calcium level may be low and produce tetany. With prolonged derangement of calcium-phosphorus balance, serious bone damage may occur, often referred to as "renal rickets" in the young child and "osteitis fibrosa cystica" in the older child.

The uremic patient is drowsy, complains of headache, and finally becomes comatose. Pericarditis, in contrast to its frequency in the adult patient, is rare in childhood. There is a tendency to hemorrhage, especially in the gastrointestinal tract.

Muscular twitchings are common and may be painful, and there may be convulsions. There is little evidence that retention of creatinine, uric acid, urea and amino acids is responsible for the syndrome of uremia. Other end products of protein metabolism such as guanidine, however, have been thought to play a part in its production. Hyperkalemia may result in severe cardiac dysfunction.

In the "crush syndrome" (lower nephron nephrosis) with severe shock, when there is

extensive leakage of plasma, there is reduction in plasma volume and severe oliguria. Vomiting accentuates the dehydration. The urine contains albumin and casts and a brown sediment of acid hematin granules. Nitrogen retention may be considerable. As the renal symptoms progress, the blood pressure rises. The serum potassium level may be high, associated with electrocardiographic changes. Renal function may be impaired for months; in other instances the salient feature may be rapidly progressing renal failure which may lead to death in uremia. Complete recovery can be expected in the reversible lesions.

Renal insufficiency secondary to tubular blockage by precipitation of sulfonamide crystals is an occasional complication of chemotherapy. In addition to this evident mechanical injury, there have been a number of instances of renal tubular damage resulting in renal insufficiency without evidence of crystalline precipitation. In many ways the renal lesion is similar to that seen in the "crush syndrome." A tendency to sodium and chloride retention has been noted in association with this disturbance. So-called salt-losing states may develop during the recovery phase of lower nephron nephrosis and may dominate the clinical picture.

The so-called transfusion kidney and the renal lesion associated with other forms of hemoglobinuria may produce a similar clinical picture.

**Treatment.** During acute uremia from any cause frequent blood chemical determinations are necessary for guidance in therapy. Water and sufficient sodium chloride must be administered to restore the depleted levels in the body fluids, care being taken not to over-expand the extracellular fluid compartment. Severe acidosis should be treated with sixth-molar sodium lactate. When there is a low blood calcium level, alkali therapy may induce a severe form of tetany by decreasing the ionization of the available calcium. Alkali should therefore be given with caution, and calcium gluconate should also be administered. Bywaters advocates the use of alkali in the treatment and prevention of the renal lesion of the "crush syndrome" in order to forestall precipitation of acid hematin granules.

In the presence of oliguria during renal insufficiency the giving of excessive amounts of fluid is dangerous. The total fluid intake should be limited to an amount equal to the daily urinary output plus the estimated insensible loss (approximately 300 cc. in a

child weighing 10 kg. to 800 cc. in an adult). If vomiting develops, more fluid may be needed. Daily accurate weighing of the child can provide an estimate of fluid needs. A loss of 100 to 200 gm. a day is well tolerated. The administration of glucose decreases tissue breakdown and ketosis. Transfusions of blood and plasma should be used to overcome shock, hemoconcentration and/or severe anemia. Fewer reactions occur in chronic nephritis when fresh blood or fresh packed cells are used. Recovery from anuria of several days' duration is not unusual and is possible even when it persists as long as two weeks. It is important, therefore, that therapy should be conservative. The so-called artificial kidney has been improved technically and in the hands of an experienced person may be a useful adjunct when the patient's clinical and chemical situation deteriorates to a dangerous degree.

When diuresis sets in, during recovery in so-called lower nephron nephrosis, large volumes of dilute urine are passed and electrolytes "washed out"; these must be replaced. In patients with chronic renal insufficiency the sodium, potassium and chloride losses may be great and must be restored by oral feeding. Hyponatremia and hypochloremia are commonly attended by a fall in glomerular filtration rate and oliguria despite a normal fluid intake. Patients who have been greatly depleted may present the manifestations of adrenal insufficiency.

In chronic renal acidosis oral alkali therapy is of value and should be continued as long as the acidosis exists. Aluminum hydroxide is administered orally to reduce phosphate absorption from the intestinal tract in order to retard the development of hypocalcemia, and calcium therapy may be indicated.

#### DISEASES OF THE RENAL TUBULES

The various functions of the renal tubules in regulating the biochemical status of the body (see renal physiology, p. 1005) may be individually altered by acquired or congenital disease and produce a number of distinctive syndromes. The list of such syndromes is steadily increasing with improved knowledge of renal physiology and cellular biochemical mechanisms.

For example, the following diseases, most of which are described elsewhere, are due in part or totally to renal tubular defects: baselosing nephritis (hyperchloremic acidosis, Lightwood syndrome, Albright syndrome),

vitamin D-refractory rickets; Fanconi-de Toni-Debré syndrome; rickets associated with congenital glaucoma (Lowe), cystinosis, cystinuria, glycogen storage disease, Wilson's disease, renal glycosuria, renal diabetes insipidus, lead and other toxic poisoning, including vitamin D intoxication, aldosteronism and chronic potassium deficiency (kaliopenic nephropathy).

In chronic undernutrition in infancy, usually secondary to diarrheal disease, there may be a reduction in glomerular filtration rate, in renal plasma flow and in tubular concentrating capacity. In severe dehydration and acidosis of acute diarrheal disease in infancy, renal tubular concentrating capacity (passage of a dilute urine) may be temporarily lost.

### SUPPURATIVE NEPHRITIS

#### (ABSCESS OF THE KIDNEY)

Although suppurative nephritis occurs most often in adults, it may occur in the newborn period and at any age thereafter.

**Etiology.** The infection may be hematogenous in origin, or it may reach the kidney by contiguity from another suppurating lesion; or it may result from the presence of a calculus, from trauma or from urinary obstruction secondary to a congenital anomaly. Many microorganisms may be causative, but the more common ones are the *Streptococcus*, *Staphylococcus* and colon bacillus. Pathologically, the lesions vary somewhat with the origin. In those of hematogenous origin both kidneys are usually involved, with numerous abscesses of varying size. At times there may be a localized abscess (*renal carbuncle*), the remainder of the renal structure being normal.

**Clinical Manifestations.** The symptoms of suppurative nephritis, when it is a manifestation of another severe infection, are overshadowed by those of the primary infection. Only when these are in the renal region and blood and pus in the urine is the diagnosis possible. In cases of abscess secondary to pyelonephritis the urinary findings are inconclusive. If the abscess is walled off, the urine may be normal.

**Prognosis.** The prognosis is unfavorable in the metastatic cases, and the course is usually short. In other forms the outlook is grave, being best when there is free communication with the urinary tubules to afford drainage. A perinephritic abscess may develop, or the pus may burrow beyond the perinephritic region.

**Treatment.** The treatment for abscess of

the kidney, which is part of a general septicemia, is primarily that of the general infection. Operative removal of an abscessed kidney may be indicated when it is reasonably certain that the other kidney is healthy. Appropriate antibiotic therapy is indicated in all instances.

### TUBERCULOSIS OF THE KIDNEY

Tuberculosis of the kidney is uncommon in early life except as a manifestation of generalized miliary tuberculosis. Pathologically, it is manifest by the presence of small tubercles developing on the surface and in the parenchyma of the kidney. There are rarely any symptoms related to the kidney.

*Localized tuberculous lesions of the kidney* are rare in infants and children. They are usually unilateral. The renal lesion may develop by contiguity from a tuberculous pleuritis or peritonitis or another lesion in the urinary tract, but it usually is hematogenous in origin.

There may be no symptoms, but most often there are general symptoms of fever, emaciation and the like and localized ones as pain, tenderness and enlargement in the renal region. There is frequent and painful urination, the urine being acid and usually containing blood, pus and tubercle bacilli. A persistently sterile pyuria is suggestive of tuberculous infection. The duration of caseous renal tuberculosis depends upon the local lesion and upon the course of tuberculous lesions elsewhere in the body.

Renal tuberculosis may be differentiated from pyelonephritis by the discovery of tubercle bacilli in the urine. Occasionally, urographic studies aid in the diagnosis by showing deformity of the renal pelvis with cystic malformations. Tuberculosis of the bladder can be detected by cystoscopic examination; its presence is presumptive evidence of renal involvement. The function of the individual kidney may be tested by ureteral catheterization. However, the renal function may be good even though the kidney is diseased.

In examining the urine for tubercle bacilli care must be taken to differentiate them from smegma bacilli; culture of the urine on appropriate media and testing for virulence in guinea pigs are required.

**Treatment.** All possible means must be used to sustain the general health. Operative removal is indicated in extensive unilateral lesions, if the other kidney is shown to be functioning normally and is not infected.

Streptomycin and isoniazid should be used with or without para-aminosalicylic acid (p. 464).

## HEMORRHAGIC INFARCTION OF THE KIDNEY

### (THROMBOSIS OF THE RENAL VEIN)

This condition usually occurs in the early weeks of life. It is usually associated with thrombosis of the renal veins, although it may occur in the absence of demonstrable thrombosis. Conversely, thrombosis of the renal vein may occur without hemorrhagic infarction of the kidney.

Thrombosis of the renal veins is rarely primary and is usually secondary to an infectious process in some other part of the body, often an enteritis. The symptoms may be masked by the primary infection, but the sudden appearance of albumin and blood in the urine of an infant with severe dehydration secondary to diarrhea is sufficient reason to consider renal thrombosis in the differential diagnosis of the renal lesion. Oliguria is common, and there may be such additional manifestations as sharp pains in the loin and the sudden development of a large, tender mass in the renal area. In about half the cases the thrombosis is unilateral. Operation is advised when the disease is apparently unilateral as demonstrated by physical examination and direct urologic studies.

Thrombosis of the renal veins may result in the nephrotic syndrome.

## RENAL CALCULUS

**Etiology.** Uric acid infarction of the kidney in the newborn infant was mentioned on page 1010. Renal calculi may occur in infants and children of all ages. Calculi are found more frequently in some geographic regions than in others, and an inherited tendency has been observed. Suppuration of bone, prolonged recumbent posture, and infection of the urinary tract may be contributing factors. Precipitation of the acetyl forms of sulfonamides in the kidney may produce obstruction. Urinary calculi are common in parathyroid disease, in cystinuria and in renal tubular insufficiency with associated acidosis and an alkaline urine. A condition described as *oxalosis* is associated with widespread deposits in the tissues of calcium oxalate crystals.

**Pathology.** The calculi consist most often of uric acid or its salts, although they are occasionally made up of oxalates, phosphates, carbonates, cystine or xanthine. Of over 500 calculi removed from children, 58 per cent were composed of uric acid or urates and 33 per cent of phosphate of lime. The stones vary in number and in size from that of gravel to calculi which fill the entire pelvis of the kidney. In about 20 per cent of cases both kidneys are involved. There may be inflammation of the tissue surrounding stones in the renal parenchyma and in the urinary tract.

**Clinical Manifestations.** Characteristic symptoms are tenderness in the renal region, pyuria, hematuria, attacks of renal colic with pain radiating to the lower part of the abdomen, the testicle, penis and thigh, and a frequent desire to urinate. Vomiting may occur with the renal colic, and there may be convulsions and collapse. The attack lasts for a few hours or sometimes, with remissions, for several days. The calculus may return to

the pelvis of the kidney, or advance and be passed into the bladder and later voided as a single stone or as gravel. The description given applies to typical cases; in infancy, symptoms may be absent or indefinite, and the pain of renal colic may be misinterpreted as intestinal in origin. In other instances there is hematuria without colic, particularly when the calculi are in the substance of the kidney. Infection of the urinary tract is often present and may dominate the clinical picture. Roentgenograms and pyelograms are of value, except in the case of uric acid stones, which do not cast a shadow. The appearance of uric acid crystals in the urine does not necessarily mean that they have been passed from the kidney, since they may have been precipitated after the urine was voided.

**Prognosis.** The prognosis is usually good in children when there is no systemic disease (see p. 1223). There is a tendency for new calculi to form. If the stone is impacted, pyonephritis or hydronephrosis may develop. In long-standing cases renal function may be permanently impaired.

**Treatment.** During attacks of colic, morphine and atropine can be administered. Ureteral catheterization may be necessary to dislodge an impacted stone. Persistent renal stones should be removed surgically. After an attack any infection of the urinary tract should be treated, and an attempt made to discover whether other stones are present. To aid in preventing recurrence, water should be taken freely. If the stone passed is composed of uric acid, it may be advisable to keep the reaction of the urine alkaline and to avoid excessive ingestion of meat. In the case of phosphatic calculi the urine should not be alkalized. When calculi result from tubular dysfunction with loss of base producing an acidosis, alkali therapy may be helpful (see p. 1223). Such foods as rhubarb, eggplant, spinach and asparagus increase the urinary excretion of oxalates.

# DISTURBANCES OF THE URINARY BLADDER

For Exstrophy of the Bladder, see page 1024.

## VESICAL CALCULUS

About two thirds of urinary calculi are found in the bladder. Vesical calculi during childhood are most common from the age of two to seven years, and occur oftener in boys, inasmuch as the short, wide female urethra permits stones to be passed while they are still small. The calculus is usually formed in the kidney, but increases in size in the bladder. Occasionally a foreign body introduced into the bladder forms the nucleus for a stone.

The *symptoms* are vesical irritability, enuresis and often attacks of pain, especially at the close of micturition, which is felt in the neck of the bladder or at the end of the penis, or in the vagina, rectum or perineum. Tenesmus is frequent both on urination and defecation, and may produce prolapse of the rectum. There may be a sudden arrest of micturition, accompanied by severe pain and straining. Pain may be relieved by having the child void while lying down if the stone is not lodged in the urethra. Priapism is common, and incontinence may occur. If cystitis develops, the symptoms are accentuated, and the urine contains mucus, pus and red blood cells. The only positive *diagnosis* is by cystoscopic or roentgenographic examination. The *prognosis* depends upon the size of the stone and upon treatment. *Medical treatment* is similar to that for renal calculi. Large stones must be removed surgically, smaller stones by crushing.

## FOREIGN BODIES IN THE BLADDER

Occasionally boys and girls, especially at the age of puberty, introduce foreign bodies into the urethra, and these may pass into the bladder. The nature of the bodies is varied, among them being hairpins, pencils, shot, beads, and the like. They may give rise to inflammation or form the basis of a calculus. Irritation of the bladder may also result from a foreign body which has been inserted and withdrawn. *Treatment* usually consists in removal through the operating cystoscope, or surgical removal if necessary.

## CYSTITIS

Cystitis as an isolated infection is uncommon; it is usually secondary to a pyelonephritis or

an obstruction at the neck of the bladder or in the urethra (p. 1026). Other causes include vesical calculi, foreign bodies, tumors, rupture of an abscess into the bladder or extension of a gonococcal infection. Actually the bladder is relatively resistant to infection; if an associated infection is controlled or an obstructing or irritating lesion removed, the cystitis tends to disappear spontaneously except when there are extensive changes in the vesical wall in long-standing infections. A rare form is *cystitis emphysematosa*, in which there are gas-containing vesicles in the wall of the bladder.

The constitutional *symptoms* include fever, restlessness and anorexia. The local disturbance varies in intensity, being greater in older children, in whom there is pain and tenderness in the region of the bladder and painful and frequent urination. The straining may produce prolapse of the rectum, and there may be constant dribbling of urine. In infants the painful urination may be evidenced only by crying. The urine is cloudy and contains white and red blood cells, mucus, vesical epithelium, bacteria and albumin. The *diagnosis* is established by cystoscopic examination. An acute, apparently infectious, *hemorrhagic cystitis* is occasionally seen in infants and children as well as in adults. Low grade fever, urinary frequency and dysuria are common manifestations. Bacteria are not usually isolated from the urine, and the possibility of a viral etiology has been considered. Gross bleeding may last for several days, and acute glomerulonephritis must be differentiated. The lesion tends to be self-limited.

*Treatment.* The only effective treatment for the secondary infections is removal of the cause. In acute cases bed rest is required, and the child should be encouraged to drink large amounts of water. Bacterial infections should be treated with a sulfonamide or an appropriate antibiotic in full therapeutic doses. Pain and straining may be relieved by hot or cold applications over the bladder or by administration of opiates or other analgesics. In severe and obstinate cases, lavage may be indicated.

## TUBERCULOSIS OF THE BLADDER

This infection, infrequent during childhood, may exist with tuberculosis of other parts of

the genitourinary system, especially the kidney, or it may be the only tuberculous lesion in the urinary tract. The lesion may consist of scattered, grayish, caseous nodules, or of ulcers in the mucous membrane. The *clinical manifestations* are those of chronic cystitis with hematuria. The *diagnosis* can be made by the discovery of tubercle bacilli in the urine and by cystoscopic examination.

### SPASM OF THE BLADDER

This symptom is more frequent in early childhood than later. Among causes are sudden chilling of the body, vesical calculus and secretion of highly concentrated urine. It may also be a reflex symptom of renal calculus or disorders of the rectum, vulva, urethra, hip

joint, appendix or other neighboring structures. There may be a spasm of the sphincter, and the child is unable to void; more commonly there is irritation of the detrusor apparatus, resulting in frequent emptying of the bladder. In the former instance there is pain and straining without passage of urine. In the latter the urine is passed frequently, sometimes only in drops, and there may or may not be pain.

*Treatment* consists in elimination of the cause if possible. When the urine is highly acid, alkalis may be given, water should be ingested freely, and atropine with or without a sedative may be administered. During spasm of the sphincter hot compresses may be applied over the bladder, or the child may be placed in a warm bath. Catheterization is rarely required.

## MALFORMATIONS AND DISEASES OF THE MALE AND FEMALE GENITAL ORGANS

### ADHERENT PREPUCE

In the majority of newborn male infants there is some adherence between the inner lining of the prepuce and the glans. When this persists after the first months of life, it may be considered pathologic. The adhesions may be complete or involve only the posterior part of the glans. The smegma collects behind the corona and may cause irritation, leading to a balanitis. At three to four months of age the adherent prepuce of the noncircumcised infant should be gently retracted, breaking the adhesions, if necessary, with a blunt probe. The glans is then cleansed, a bland ointment applied, and the foreskin returned over the glans. After this the prepuce may be retracted during the bath so that the sulcus behind the corona can be cleansed.

### PHIMOSIS

Phimosis is a narrowing of the preputial opening such that retraction of the prepuce is impossible. Rarely there is no opening whatsoever. The prepuce may be of normal length or much elongated and hypertrophied (*redundant prepuce*); the latter is not necessarily accompanied by phimosis. When the opening of the prepuce is small, urination can be accomplished only by straining; the urine is voided in drops or a small stream.

If adhesions are not present, the foreskin during micturition is ballooned by the urine beneath it. Hernia or prolapse of the rectum may be produced by the straining, and there may be infection of the urinary tract. Concretions may form under the prepuce.

*Treatment* by forcible retraction or stretching with dressing forceps is often sufficient, or the preputial orifice may be widened by incision; in severe forms circumcision is indicated. A redundant prepuce without phimosis does not necessitate circumcision.

### PARAPHIMOSIS AND STRANGULATION OF THE PENIS

In this condition the prepuce which has been retracted beyond the corona cannot readily be replaced. The circulation in the glans is interrupted by the constriction; edema, bluish discoloration and even gangrene may develop. Pain and dysuria are usually severe. The accident usually follows retraction of the prepuce by the patient himself or by the mother or nurse when cleansing the penis. Cold compresses should be applied to reduce the swelling, and an effort made to draw the foreskin forward into the normal position. To aid in this the glans should be well oiled and steadily compressed, and the forward pull should be as evenly placed around the constricting prepuce as possible. If this pro-

cedure does not succeed, incision of the constricting ring of skin at the rear of the swelling may be required. If the foreskin is unduly narrow, circumcision should be performed after the inflammation has subsided.

A condition similar to that of paraphimosis may be produced if the patient ties a string around the penis or slips a ring or other object over it. Treatment consists in division of the constricting body and application of cold compresses.

### ABNORMAL SIZE OF THE PENIS

The size of the penis varies greatly. At times in the prepuberty period the penis appears to be unusually small, owing to a large deposit of fat in the mons and scrotum, which partially buries it from view. In rare instances it may remain a rudimentary structure, and on occasion surgical intervention may be necessary, owing to obstruction of urinary flow. The penis may become greatly hypertrophied in certain cases of physical precocity (p. 1157). Congenital absence of the penis is rare, and rarely it is displaced from its normal position. The penis may be duplicated, usually in association with duplication of the bladder. Torsion of the penis may be associated with hypospadias.

### BALANOPOSTHITIS

Inflammation of the prepuce (*posthitis*) and glans (*balanitis*) is most often produced by phimosis, resulting in retention of smegma. It may follow injury by masturbation or other means, or it may occur as a complication of urethritis. Diphtheritic balanoposthitis is rare. The prepuce becomes red and edematous, and itches; the orifice is narrowed, and there is a purulent secretion from the inflamed mucous membrane. There is dysuria and cystitis; hydronephrosis may be a complication in severe cases. In ordinary cases the inflammation lasts but a few days. *Treatment* consists in administration of an appropriate antibiotic. Cold compresses should be applied to reduce the swelling. In extreme instances splitting the foreskin or circumcision is necessary in spite of the infection present.

### MALFORMATIONS OF THE URETHRA

#### HYOSPADIAS

In this congenital malformation the urethra does not extend the entire length of the

penis, but opens on its lower surface just behind the glans, in the body of the organ or, in extreme cases, in the perineum, or at times as a fissure, the scrotum being split in half. There is usually some degree of congenital chordee. Since the penis is usually rudimentary in the severe cases, and the testes undescended, the appearance of the external genitals simulates that of the female (*pseudohermaphrodisim*). Only the severe forms interfere with procreation. *Treatment* is surgical, and in many cases a plastic operation is successful. In the mild cases no treatment is necessary. One should be certain that the opening is sufficiently large to permit free urinary flow.

Rarely an analogous condition is seen in girls, the opening of the urethra being within the vagina beneath the hymen.

#### EPISPADIAS

In this uncommon congenital anomaly the opening of the urethra is upon the dorsal surface of the penis. It may be small and situated just behind the glans; in the more extreme varieties it may take the form of a fissure extending the entire length of the penis in combination with exstrophy of the bladder. Treatment is surgical.

#### OTHER ANOMALIES

Congenital atresia of the urethra may vary from mere closure of the meatus by adhesions to complete obliteration. A patulous urachus or exstrophy of the bladder may accompany the latter. There may be a congenitally narrow urethra, perhaps only at the meatus, or a cylindrical narrowing of some part of the canal. Congenital stricture of the meatus in the female is an occasional anomaly. Acquired stricture may be the result of gonorrheal urethritis or rarely of cicatricial contraction from other causes. Urethral diverticulum or a valvelike obstruction of the posterior urethra is not uncommon. The end results of urethral obstruction of any sort, if continued, are dilatation of the bladder and ureters and hydronephrosis. Fusion of the urethra and intestine may occur. Urethral fistula is rare, and may be congenital or due to injury by a calculus or foreign body in the urethra, or to trauma. The external opening of the fistula may be in the penis, in the perineum or elsewhere. Double urethra and persistent cloaca have been described.

## INFLAMMATION OF THE EXTERNAL

### URETHRAL ORIFICE

This lesion, often a manifestation of amoniacal dermatitis, is apparently confined to circumcised infants. It causes dysuria and a tendency to retention of urine. Superficial ulceration of the orifice may be produced. A thick layer of bland ointment should be applied locally, and the diaper should not be tight-fitting (see p. 1298).

### URETHRITIS

Urethritis is not common in early life. It may be due to extension of inflammation from balanoposthitis, to irritation by highly acid urine, to introduction of foreign bodies into the urethra or to other onanistic acts. Urethritis due to the *Gonococcus* is seen oftener in females, in whom it is secondary to gonorrheal vaginitis, but by no means a common complication. The *symptoms* are dysuria, swelling and redness of the urethral orifice, and discharge of pus from it. In the non-gonorrheal lesion the course is usually short; in the untreated gonorrheal infection it is longer, and balanitis, proctitis, epididymitis, arthritis, conjunctivitis and prostatic abscess are possible complications. Stricture may be a sequel. An etiologic *diagnosis* should be established by bacteriologic culture. *Treatment* consists in keeping the parts clean and in administration of an appropriate antibiotic. A protective dressing should be worn to prevent extension of the infection and the carrying of it to the eyes.

### FOREIGN BODIES IN THE URETHRA, INCLUDING URETHRAL CALCULUS

A stone, after its passage from the kidney and bladder, may become impacted in the urethra, most often in the membranous part of the penis. Foreign bodies may be introduced into the urethra during later childhood and become impacted there. The *symptoms* depend somewhat upon the size and kind of stone or foreign body. There is dysuria and obstruction to the flow of urine. Urethritis may develop, at times with periurethritis and infiltration of urine into surrounding tissues; the flow of urine may then be completely obstructed. The detrusor force of the bladder may finally succeed in expelling smooth calculi and foreign bodies, but frequently surgical intervention is necessary.

## INFLAMMATION OF THE SCROTUM

The most common cause of scrotal inflammation in infants is uncleanness, but the scrotum may also be the site of eczema, erysipelas and secondarily infected scabies, or it may be involved by contiguity from inflammatory lesions of neighboring structures. The skin is intensely red, and the tissues, owing to their laxness, are often considerably swollen. *Treatment* consists chiefly in cleanliness and in keeping the scrotum dry with mildly antiseptic powders and in leaving the parts exposed to the air. In severe inflammation antibiotic therapy may be indicated. Eczema, erysipelas and scabies require special treatment, which is described under the respective headings of these diseases. Surgical intervention is necessary if there is abscess formation.

### GENITAL EDEMA OF THE NEWBORN INFANT

The cause of this unusual condition is not understood. The condition may possibly be due to the action of an estrogenic substance transmitted in utero by the mother. It occurs especially in premature infants, and consists in noninflammatory edema of the entire genital region, at times extending over the abdomen and thighs, and appearing at any time in the first month or two of life. It usually disappears within a few days, but may last a month or more. The disorder is differentiated from sclerema by its localization and the good general condition; from erysipelas by the lack of local and general evidences of infection. No particular treatment is indicated.

### UNDESCENDED TESTES

#### (CRYPTORCHISM)

The testes should descend into the scrotum in the eighth month of fetal life, but arrest in the descent of one or both testes takes place in about 0.1 to 0.7 per cent of male infants, and one or both organs may remain in the abdomen or, more frequently, in the inguinal canal. Careful examination is necessary before a diagnosis of cryptorchism is made since the testes are frequently out of the scrotal sac in children under normal circumstances. Infrequently they may be situated in some abnormal position, most often in the perineum. A testis retained in the inguinal canal may

descend into the scrotum in the course of weeks or months or at any time up to puberty. When in the inguinal canal, the testis is a small, movable body and may be mistaken for a hernia, by which it is accompanied in half or more of the cases. There may also be an associated hydrocele or torsion of the spermatic cord. A testis remaining persistently out of place finally becomes atrophic and does not produce sperm, but the interstitial cells are usually not affected. In persistent bilateral cryptorchism the adult will probably be sterile, but the development of masculine characteristics is usually normal. Psychologic disturbances may occur in late childhood.

*Treatment* is not required in infancy, since the testes may descend spontaneously. There is lack of unanimity about a plan of therapy. Some recommend early treatment despite the fact that in about two thirds of instances testes undescended at birth will descend spontaneously by the completion of puberty. Early treatment is designed to prevent "unjustifiable" hazards and the possibility of aspermatogenesis of the involved testis. Wilkins does not believe that available evidence justifies this assumption. When there is a demonstrable hernia, the testis can be anchored in the scrotum when the hernia is repaired. In bilateral cryptorchism Campbell recommends trial with hormonal therapy for two or three weeks by about three or four years of age; if treatment is not successful in bringing the testes into the scrotum and/or if they do not remain there, surgical correction is then carried out. In unilateral cryptorchism he feels there is less urgency for treatment even though there is the possibility of atrophy in the undescended testis. Others recommend that therapy be deferred until the prepuberty age, ten to twelve years. If hormonal therapy is to be tried, an accepted dose of gonadotropin (Antuitrin-S) is 500 to 1000 units three times a week for four or five weeks. Larger doses administered over a longer period are not likely to be more beneficial and may be harmful. It is likely that favorable results are obtained only when descent would have occurred spontaneously at puberty. Testosterone has been used, but is no more effective than gonadotropin and has greater potentiality for harm. Failure of response to hormonal therapy is indicative of mechanical interference or testicular absence. In all cases of mechanical interference orchidopexy should be performed.

## POLYORCHISM AND ANORCHISM

Polyorchism, more than the normal number of testes, and anorchism, absence of the testes, are extremely rare anomalies.

## ORCHITIS AND EPIDIDYMITIS

Acute orchitis occasionally occurs in boys as the result of trauma, rheumatism or infectious fevers, especially mumps. Mumps orchitis (p. 505), however, is rare in comparison with its incidence in adults. Gonorrhea is more liable to produce epididymitis than orchitis. Epididymitis may also be caused by the Staphylococcus, Streptococcus, colon bacillus and other organisms. The *prognosis* of both orchitis and epididymitis is generally favorable unless suppuration occurs, when atrophy and subsequent sterility of the involved side may result. The testes should be elevated, cold wet dressings applied, and an antibiotic administered. Syphilitic orchitis runs a more chronic course, is painless, and does not suppurate.

## TORSION OF THE SPERMATIC CORD

Torsion of the spermatic cord is more common in incompletely descended testes than in those residing in the scrotal sac. Sloughing, infection and subsequent atrophy may occur. Torsion must be differentiated from epididymo-orchitis, strangulated hernia and inguinal adenitis.

## HYDROCELE (See page 691)

## TUBERCULOSIS OF THE MALE GENITAL ORGANS

Primary tuberculosis of the penis has been acquired from the older form of ritualistic circumcision. This is extremely rare in modern practice. Tuberculosis of the testis is rare in infants and children. It is usually unilateral; trauma may be a predisposing factor. The testis and the epididymis become enlarged and hard, and the scrotum is discolored. The process may undergo absorption, but, especially in infants, is more likely to become caseous and liquefy. The course is protracted, the *prognosis* being dependent on both the local lesion and whether the tuberculous process has extended to other parts of the body. A locally infected testis may be removed, provided the other testis is pre-

sumed to be uninvolved and the general condition warrants the surgical procedure. Treatment with streptomycin and isoniazid should be instituted before and for several months after the surgical removal (p. 464). When surgery is not feasible, drug therapy may be tried.

## MALFORMATIONS OF THE VULVA, VAGINA AND CLITORIS

Atresia of the vulva is rare, but epithelial adhesions of the greater or lesser labia are common. Even though the adhesions are not completely obstructive, they may cause retention of mucous secretions, and later of the menstrual discharge; and, if complete, they also interfere with urination. Retention of menstrual discharge is also produced by an imperforate hymen. There may be partial or complete absence of the vagina. It may be divided into two compartments by a membranous partition, or there may be two complete vaginas. Malformations of the vulva and vagina are often associated with those of the rectum, anus and bladder, and communication may exist between the vagina and the rectum or bladder.

There is frequently adherence between the labia and the clitoris, sometimes causing irritation from retained smegma, which may be responsible for the instigation of masturbation. Congenital fissure of the clitoris is rare and may occur in combination with a fissure of the urethra.

Adhesions between the labia or between the labia and the clitoris may be broken with a probe; an imperforate hymen should be ruptured.

## VULVOVAGINITIS

Vulvovaginitis is a relatively common infection which may be divided into two categories: nongonorrheal and gonorrheal.

### NONGONORRHEAL VULVOVAGINITIS

**Etiology.** Infections of the vagina may occur at any age and be caused by practically any pathogenic organism. Herpetic lesions may occur, and rarely diphtheria is localized in the vagina. *Trichomonas* vaginitis occurs infrequently before puberty; vaginal thrush is seen on occasion in weak and sickly infants. The vesicles of varicella may appear upon the mucous membrane of the vagina, and in measles a catarrhal inflammation may de-

velop. During various acute infections, including upper respiratory ones, there is evidence of vulvovaginal inflammation which tends to subside with recovery from the systemic infection. In undernourished or debilitated girls or when hygiene is poor, the genital infection may be persistent.

Predisposing factors include tight undergarments, uncleanness, traumatism, masturbation, eczema, threadworms and various foreign bodies in the vaginal canal.

**Clinical Manifestations.** The symptoms of vaginitis are redness and swelling of the genitals. There is a vaginal discharge which is scanty or abundant, thin or purulent and often offensive in odor.

**Differential Diagnosis.** Differentiation from gonorrheal vaginitis depends upon bacteriologic studies. In vaginitis dependent on the *Trichomonas* there is a foamy leukorrhea, and the active flagellate parasites can be found in vaginal smears. *In all instances of persistent vaginal discharge the possibility of a foreign body must be investigated by direct inspection through a speculum and/or roentgenographically.*

**Prognosis.** If the cause can be removed, the prognosis is good, but in debilitated children the discharge may continue for a long time in spite of treatment.

**Treatment.** Treatment is directed primarily at removal or correction of the predisposing or underlying factor and at improvement in the general health. Cleanliness of the genital region is of the greatest importance. In thrush vaginitis a 1 per cent aqueous solution of gentian violet may be used locally, or Mycostatin can be used locally and systemically. In *Trichomonas* infection lactic acid (0.5 per cent) douches are used, or acetarsone in powder form may be insufflated into the vagina. In bacterial infections appropriate antibiotic therapy is indicated.

### CONORRHEAL VULVOVAGINITIS

This condition, once comparatively common in the first five years of life, is now relatively uncommon.

**Etiology.** In infants the disease may be acquired during the process of birth, or later from a mother with a gonorrheal discharge; or it may be spread in other ways, as by the hands or garments of the attendant or by infected bath tubs, diapers, bedclothing, washcloths or thermometers. Contraction of the disease by any sort of sexual act is uncommon in children.

**Clinical Manifestations.** In mild cases

there may be only a small amount of thin discharge, but in more severe ones there is an abundant, yellow, purulent discharge. The mucous membranes of the vulva and vagina are inflamed, and there may be involvement of the urethra and of the rectum. Ordinarily there is little or no discomfort, but in severe cases there may be fever, dysuria, and excoriation of the skin of the vulva and thighs.

**Diagnosis.** All leukorrheal discharges, particularly in infancy and early childhood, should be considered gonorrheal until proved otherwise. Material for examination should be secured from the vagina itself or the cervix of the uterus, using a speculum or a small vaginoscope. Another procedure is to irrigate the vagina with a small amount of physiologic saline solution and then examine the sediment obtained by centrifugation. The bacteriologic examination should include a *culture* as well as a direct smear.

**Complications.** Serious complications are much less frequent than in adult life and occur chiefly in later childhood. The more common complications are inguinal adenitis, urethritis and proctitis; much less common are cystitis, pyelonephritis, endometritis, salpingitis, peritonitis, arthritis, septicemia and ophthalmia. A careful inspection of the vagina should be made in every case of suspected peritonitis in girls.

**Prognosis.** Although seldom serious, without effective treatment the infection is often prolonged and is a source of great anxiety. It tends to clear up spontaneously, but usually not before puberty. It apparently does not cause sterility and rarely leaves other residuals. Therapy with penicillin is highly effective, and cure can be expected in most instances within a few days.

**Prophylactic Measures.** It is good practice to inspect the vagina during all physical examinations; if there is evidence of inflammation, a bacteriologic examination should be made. It should be remembered that urethritis in the male or proctitis in either sex may be gonorrheal in origin.

Hospitals should provide individual thermometers, bedpans and other toilet articles for all children. A single-service diaper made of cotton, absorbent gauze, or paper, which can be destroyed afterwards, may be used instead of the ordinary textile one; or the latter, if used, may be disinfected before being sent to the general laundry. A U-shaped toilet seat should be provided for older infants and children, and individual paper pro-

tectors used. Spray baths are preferable to tub baths.

A patient with vaginitis or other gonorrheal discharge must be completely isolated from other children, since even the greatest precautions will not always prevent spread of the disease within a hospital ward or other unit of a hospital.

When a case develops in an institution other than a hospital, the same principles should be followed. School authorities should be familiar with the disease and its implications. All children with known gonorrheal vaginitis should be excluded from school until cure is effected.

**Treatment.** Scrupulous local cleanliness should be observed, but douching is not indicated. Sulfonamides are effective in most instances, but penicillin would appear to be the drug of choice. Daily doses of 300,000 units should be continued for four or five days. A bacteriologic examination should be obtained two weeks after completion of therapy. There is little or no place for estrogenic therapy.

## ABSCESS OF THE VULVA

Abscesses are usually secondary to trauma, erysipelas, or extension of inflammation from a vaginitis. The external labium on one or both sides becomes red, tender and swollen, and suppuration usually occurs. The general constitutional symptoms of infection are present. *Treatment* consists in application of hot compresses, and in incision when necessary. Sulfonamide and antibiotic therapy is of distinct value.

## GANGRENOUS VULVITIS

Gangrenous vulvitis is analogous to noma of the mouth. It occurs in malnourished children, especially after such infectious diseases as measles or erysipelas, or it may follow herpetic vulvitis. Spirochetes and fusiform bacilli may sometimes be found. A swollen, tense, dark red area which proceeds to gangrene appears on one of the external labia. In severe cases the process spreads with great rapidity. There is pain, fever and great prostration, often followed by death. In mild cases the process is limited to a small area which heals with cicatricial deformity. *Treatment* in the past consisted in supportive measures and prompt excision followed by cauterization. It seems probable, however, that antibiotic therapy may decrease the need for such radical measures.

## GENITAL HEMORRHAGE; PRECOCIOUS MENSTRUATION

Discharge of blood from the vagina other than during menstruation may result from inflammation, injury, foreign bodies, neoplasms, or asphyxia at birth, or may be a manifestation of a hemorrhagic disease. It may occur in the newborn as a result of the influence of maternal hormones. The blood may arise from the vulva, vagina or uterus. Precocious menstruation, in which the flow takes place at more or less regular intervals, is often accompanied by other evidences of sexual and somatic precocity (p. 1157). *Treatment* of genital hemorrhage itself is seldom needed, although the underlying cause may demand appropriate therapy.

## DISEASES OF THE UTERUS AND FALLOPIAN TUBES

The uterus may be absent, rudimentary, doubled or divided in varying degrees. One or both fallopian tubes may be absent or rudimentary. Rarely there is extension to the uterus and tubes from a gonorrheal vaginitis. In cases of imperforate hymen the vagina and uterus may become dilated by mucous or watery secretion, and after puberty a hematocolpos or hematometra may develop. Uterine prolapse is often combined with spina bifida.

Complete prolapse has been reported in the newborn. Both malignant and benign tumors are rare, but have been recorded.

## DISEASES OF THE OVARIES

One or both ovaries may be absent, or there may be accessory ovaries. *Ovarian hernia* is not rare. It may be congenital or acquired, and the ovary on one or both sides may be found in the inguinal canal, less often beneath the femoral ring, and occasionally elsewhere. In inguinal prolapse the pedicle of the ovary may become twisted and the organ strangulated. Appendicitis may be simulated.

*Tuberculosis* of the female reproductive system is uncommon, and is generally secondary to tuberculous peritonitis or enteritis, or is part of a generalized miliary infection. The internal genital organs are more frequently involved than the external ones.

*Neoplasms* are described on pages 1201 and 1358.

# The Nervous System

## DIAGNOSTIC STUDY OF NEUROLOGIC DISEASE\*

### HISTORY AND PHYSICAL EXAMINATION

The physical examination in neurologic disease localizes the disease process; the history suggests its nature. No other procedures can replace these two; carelessness, indifference or inadequacy in performing them ends in neglect of serious illness or in performance of unnecessary, painful or dangerous special procedures.

**History** (see also p. 161). As the history is taken one has opportunity to establish the beginning of a friendly relationship with the child and to observe his spontaneous behavior and activity, which suggest many of his physical signs.

Many neurologic ailments of childhood are present at birth or acquired soon after, so that, when such origins are possibilities, the family history and the details of pregnancy and labor must, if possible, be more detailed than with illnesses more clearly of recent onset. Repeated review of the history often brings out valuable information. The following outline may be expanded or reduced as circumstances indicate.

**Family history.** For parents, grandparents, aunts, uncles and cousins: present health or cause of death; symptoms similar to patient's; common neurologic symptoms, such as convulsions, visual or motor failure, disturbance of gait.

For the immediate sibship: date, parentage and outcome of each pregnancy; causes of any deaths; present state of survivors; presence of symptoms similar to patient's.

**Pregnancy.** Difficulties in conception; duration as exactly as possible; onset and quality of fetal movements; date, duration, severity, treatment and effect if noted on fetal movement and heart rate, of maternal toxemias, illness or infections, injuries, radiation,

exposure to drugs or toxins, vaginal bleeding and severe emotional stress.

**Labor.** Hour of onset and delivery (total duration); presentation; anesthesia and analgesia; operative procedures, indication for, if known; evidence of fetal distress.

**Neonatal period.** Birth weight; initial breathing and crying; cyanosis, asphyxia pallida or livida; resuscitative procedures, use of oxygen or incubator; signs of trauma; jaundice; duration and treatment of convulsions; infection; notable listlessness, vomiting, "jitteriness," stiffness or limpness.

**Growth and development.** Serial weights and heights, if available; age at puberty; age at such developmental acquisitions as social smile, sitting alone, standing, walking and the like; school progress, if any. Compare with siblings.

**Past health.** Date and severity of each significant illness, injury or operation, with special note of high fevers, delirium, head trauma, convulsions, disturbances of gait, vision or hearing, and changes of personality.

**Present illness.** List the symptoms with record of time of onset and further progression; try to document the way each came to attention. Summarize onset and principal features of each salient event of the illness chronologically.

**Technique of Physical Examination.** No rigid scheme of examination is necessary if the examiner remembers a few principles. No neurologic examination is complete without a general physical examination. A regular method of recording findings is essential for completeness and clarity. The physiologic and emotional condition of the child may affect his signs; fright, cold or embarrassment heightens reflexes and impairs fine motor performance; warmth, a full stomach, and sedatives diminish reflexes and alertness. At some time all clothing must be removed from the child; "much more is missed from not look-

\* See also page 295.

ing than from not knowing." History and physical examination generally provide a reasonable differential neurologic diagnosis. Conclusions made before these two are completed are usually erroneous. The neurologic examination includes (1) vital signs, (2) mental status, (3) gait, station and handedness, (4) cranial nerves and special senses, (5) motor system and reflexes, (6) sensory system, (7) coordinative system, (8) autonomic system, (9) special findings.

The *vital signs* require no special comment. An estimate of the *mental status* in infants is based on alertness, response to examiners and quality of cry; in older children, from the playing of simple games, inquiries about siblings, pets, illness and the like, and by formal evaluation of the intelligence. *Gait, station and handedness* are determined by simple observations.

The *special senses* should be examined early, before fatigue impairs cooperation.

**Vision.** In the infant, or child with very low vision, the ability to follow a light or to avoid threatening movements is noted. If there is real doubt as to the presence of vision, demonstration of optokinetic nystagmus is useful. A cylinder marked with alternating wide black and white stripes is rotated slowly before the child; if cortical vision is present, the eyes follow the stripes slowly, then jerk quickly back to midposition; this response appears normally within the first few weeks of life. Older children are tested with charts, or by having them pick up coins or bits of paper scattered on floor or table top; the latter procedure tests both fields and acuity.

To test *visual fields*, the child and examiner stand about 3 feet apart and cover opposite eyes, and each fixes on the other's uncovered eye. The examiner brings his finger, or other test object, inward along radii of a circle, the center of which is on the axis of fixation, midway between examiner and child. The child states when he sees the object, the examiner's visual field serving as a check. The test object should be carried inward to the center, to detect central defects. With infants or young children attention is held with a light or toy, and the hand moved in until the child notices it. Accurate visual fields can be obtained by confrontation methods alone. Color fields and perimetry may be necessary for exact work.

Ophthalmoscopy should be reserved till last with small children, who often struggle. Common errors are (1) overlooking early

papilledema, the first signs of which are not blurring of the disk margins, but dilatation of retinal veins and obliteration of the optic cup; indistinct disk margins without the other signs usually represent refractive error or congenital peculiarity. (2) Mistaking optic neuritis or pseudoneuritis for papilledema; the appearances may be identical, but loss of acuity and color vision is marked with neuritis, slight or late with papilledema. (3) Mistaking the normal grayish disk of infancy for optic atrophy.

**Hearing.** Startling or blinking at loud sounds tests only lowermost levels of the auditory system, and may persist despite cortical deafness. Turning toward a sound or smiling at a parent's voice is a better sign of hearing. Children who can speak are asked to repeat aloud numbers whispered at their ears.

**Labyrinthine function.** Hold the child aloft, his face at a level with the examiner's, who turns round rapidly several times; after three or four turns the normal child shows definite nystagmus. To test one labyrinth instill 5 to 10 cc. of iced water into the external ear with a soft catheter or syringe. Normally, nystagmus with the slow component to the stimulated side appears in about forty seconds, and persists about two minutes. Lesions of the vestibular apparatus, the eighth nerve or brain stem diminish or obliterate the response; in decortication the slow phase alone is present, and the eyes deviate to the stimulated side.

**Smell and taste.** Tests of *olfaction*, with some familiar odor, and *taste*, with salt or sugar solutions applied to the tongue, are seldom informative, and done only when first, seventh, or ninth nerve lesions are suspected.

**Cranial nerves.** To test the oculomotor group, the third, fourth and sixth nerves, observations are made for pupillary size, direct and consensual response to light and response to convergence, range of movement of eyes, ptosis and nystagmus. Tests of the facial group, the fifth and seventh nerves, include determinations of facial symmetry at rest and in movement, equality of palpebral fissures, strength of lid closure, corneal reflexes, facial sensation to pin prick and light touch, and jaw movements. For the ninth, tenth, eleventh and twelfth nerves one should note the quality of voice, gag reflex, swallowing actions and the function of the trapezii and sternomastoids. Palatal asymmetries are not significant unless marked and associated

with diminished gag reflex. The tongue should be examined carefully for size, symmetry, movement and fibrillation.

**The motor system.** The child should be observed stripped at rest, and partially clothed in spontaneous and induced activity. He is asked to lie down, stand up, hop on one foot, walk, walk tandem, run and climb stairs; he is offered some attractive toy, plays a game of catch, or writes or colors simple drawings. Note bodily proportions, spontaneity and symmetry of movements, handedness, evidence of generalized or localized weakness, steadiness of gait and presence and kind of any involuntary movement. Look carefully for the following:

#### 1. PHYSICAL STATUS OF MUSCLES.

*Atrophy* may be part of generalized wasting or may be due to disuse. If it is due to progressive motor neuron disease, it is accompanied by *fasciculations*, brief repetitive twitches, occurring at rest, increased by movement or percussion of the muscle. Completely denervated muscle *fibrillates*, producing a slow undulating movement, visible clinically only in the tongue. *Aplasia* or *hypoplasia* most frequently involves facial and extraocular muscles (Moebius' syndrome), but any muscle may be affected. Arrest of development with smallness of limbs, slight muscles, narrow nails and slender bones is seen in limbs paralyzed at an early age. *Hypertrophy* may be compensatory, as in the arms and shoulder of a patient with paralyzed legs, or result from constant overaction in choreo-athetosis. In *pseudohypertrophy* size is increased by fatty infiltration, and the muscle itself is weak.

**2. DISORDERS OF TONE.** *Tonus* is the contraction in a muscle voluntarily relaxed. It is tested by inspection and palpation of the muscle and passive movement of joints. *Flaccidity*, the absence of tone, is seen in organically or physiologically denervated muscles. *Hypotonia* is a reduction of normal tone. *Spasticity* is an exaggeration of stretch reflexes, depending on impairment of central inhibition with maintenance of central facilitation of these reflexes. It expresses itself as diminished voluntary movement and the appearance of postures in the limbs indicating movements particularly impaired. It is characterized by (1) increased resistance to passive movement, giving way suddenly when overcome—"clasp knife" rigidity; (2) increased myotatic reflexes; (3) clonus. It is not produced by isolated lesions of the motor

cortex, but rather by widespread damage to the motor system.

*Rigidity* implies increased tone and resistance, not accentuated in any particular movement. The hypertonus may appear to abolish reflexes, but they are present and increased. When overcome, hypertonus may give way in a series of brief relaxations, producing the cog-wheel phenomenon, or maintain a constant, plastic resistance.

**3. INVOLUNTARY MOVEMENTS.** *Myoclonic jerks* are brief contractions of whole muscles occurring irregularly and without pattern; massive myoclonus is a sudden jerk involving neck, shoulders and upper trunk. *Myotonus* is sustained contraction following voluntary contraction or direct percussion of the muscle. *Tremors* are usually regular movements, principally flexion-extension, of segments of limbs, entire limbs or head and trunk; the rate varies from three to ten per second. Tremor at rest, with limbs relaxed, suggests disease of the extrapyramidal system; intention tremor, or tremor on movement, indicates involvement of cerebello-rubro-thalamo-cortical circuits. *Athetosis* is an irregular wandering movement, most marked in fingers or toes. *Chorea*, often associated with athetosis, is a coarse, jerking, irregular movement involving large joints or segments of a limb. *Dystonia* is a slow, twisting movement of limbs or trunk, about the long axes of the segment involved. *Tics*, by contrast, are repetitive movements without organic dysfunction, which could be purposive, and can be stopped for a time by the patient.

**4. MUSCULAR STRENGTH.** The strength of muscles, and of particular movements, should be carefully tested. Certain patterns of weakness characterize special types of neurologic impairment. Pyramidal lesions weaken extension more than flexion in the upper extremity, while the converse is true of the leg. In polyneuritis proximal muscle groups are usually weaker than distal ones in legs, the distal ones weaker than proximal ones in the arms. Most dystrophies weaken limb girdle, axial and proximal muscles much earlier than distal ones.

**5. REFLEXES.** The stimulus for the *myotatic* or *stretch* reflexes is deformation of nerve endings in the muscle or tendon; the reflexes are segmental, with afferent and efferent neural limbs, and a segmental center within the brain or cord. They are diminished or abolished by any process which (1) impairs nerve conduction, such as peripheral

neuritis; (2) lowers the central excitatory state, such as spinal shock; (3) reduces reactivity of muscle, such as atrophy or metabolic disturbance. They are increased by processes which lower the central inhibitory state or reduce synaptic resistance, such as pyramidal tract lesions or tetanus.

The limb should be relaxed, and the muscle to be stimulated should be able to act at maximal mechanical advantage; usually this is a position of about half-flexion of the joint involved. The stimulus is a brisk tap on tendon or bony prominence, putting a muscle on stretch. The muscle itself should not be tapped. The contraction which follows is not a myotatic reflex. Reflexes should not be considered absent until reinforcement has been tried by causing muscular activity in another part of the body—having the older child squeeze the examiner's hand, or provoking the infant to tears.

The following myotatic reflexes, with their segmental arcs, are usually adequate:

<i>Reflex</i>	<i>Central Arc</i>
Jaw jerk .....	Pons
Biceps jerk .....	C 5-6
Triceps jerk .....	C 8
Supinator jerk .....	C 5-6
Finger jerks (Hoffmann sign) .....	C 8-T 1
Knee jerk .....	L 3-L 4
Ankle jerk .....	S 1-S 2

The important superficial reflexes are the plantar, abdominal, anal, and grasp reflexes.

**ABDOMINAL REFLEXES.** Stroking away from the umbilicus, horizontally, upward or downward, with a blunt point causes contraction of the homolateral abdominal muscles, with some localizing significance depending on the level stimulated. A cerebral as well as spinal arc is present, and reduction of abdominal reflexes characterizes most pyramidal lesions, though they usually persist in hemiparesis of early onset.

**ANAL REFLEX.** Stroke the perianal skin with a pin; a prompt constriction of the anus follows, mediated through the lowermost sacral segments.

**PLANTAR REFLEX.** Stroke along the lateral margin of the sole, from the heel forward, in a J curve ending medially at the base of the great toe. A reasonably firm stroke with key, fingernail or blunt pencil is best; the more lateral the stroke, the less the likelihood of avoidance reflexes. The foot should be warm and the initial strokes gentle. Three responses may occur. (1) The toes may plantar flex; this is the response in all normal waking persons over one to two years. (2) The great

toe may dorsiflex, with or without fanning of the other toes; the movement, unlike avoidance, is slow and maintained. This response, the only one properly called Babinski's sign, is evidence of structural or functional pyramidal tract deficit. A similar response occurs up to one to two years of age, and in sleep. (3) There may be no movement at all, as in spinal shock, deep anesthesia or coma or peripheral neuritis.

**GRASP REFLEX.** Stroking the palmar surface of the metacarpophalangeal joints toward the fingers brings out a sudden grasp reflex, followed by maintained contraction if the stimulus is continued. The reflex is normally present in infants under four months of age; at later ages it suggests frontal lobe lesions, though its localizing value is not absolute. When it is present, gentle stimulation of palmar and volar surfaces of fingers will bring out groping movements of the hands as well.

**The sensory system.** Awareness of pin prick, the light touch of a tuft of cotton, position of fingers and toes and vibration are all that need ordinarily be tested. Sensory findings are less reliable than motor or reflex change, and minor aberrations, unless repeatable, should be disregarded. Sensation is best tested from a suspected toward a normal area, or from the distal to the proximal portion of a limb.

**Coordinating system.** Most disorders of co-ordination are apparent in spontaneous movement. Watch the child reach for a toy, build a block house, tear paper, "do his buttons," or open and close a safety pin. Have him touch his nose and the examiner's finger alternately; move the target about, to prevent decomposition of movement and bring out ataxia. Romberg's sign, standing on either foot singly, and hopping on one foot, together with the heel-shin test, suffices for the legs.

**Autonomic system.** Color and temperature of the skin, mottling, edema and trophic sores should be looked for. Sweating, usually abolished below a transverse spinal cord lesion, may be demonstrated with the starch-iodine test (see below). A distended bladder should always be sought for; defects of sphincter function usually appear in the history.

**Special findings.** Percussion over the sphenion gives a flat note if the sutures are separated; this, *Macewen's sign*, is inapplicable to infants and unreliable in early sutural separation. In about 10 per cent of young children *auscultation* over the vertex, temples or eyeballs discloses a bruit, systolic in time

or accentuated in systole. Most bruits are innocent, transmitted from the heart or due to angulation of basal vessels; some accompany anemia, hydrocephalus or increased intracranial pressure. Rarely they indicate vascular malformations. A significant bruit is usually loud and often lateralized. Hydranencephaly, extreme hydrocephalus and sometimes subdural hematoma can be demonstrated by *transillumination of the skull* of the infant; a strong flashlight with a sponge rubber cuff about the end and a completely dark room are necessary. Sweating tests, using starch powdered over iodine dried on the skin, or an old-fashioned indelible pencil drawn from suspected to normal regions, aids in demonstrating spinal cord or autonomic lesions.

## EXAMINATION OF NEWBORN AND YOUNG INFANTS

The most constant sign of neurologic abnormality in newborn and young infants is failure of development of reflex patterns appropriate to age, and persistence, reappearance or exaggeration of less mature ones. Generalized reflex responses are more important than in examination of older children. The intrinsic reflex arcs and conducting systems through mesencephalic levels are intact and functioning at birth, and most testable reflexes are those of brain stem or spinal cord, uninhibited or only partially modified by suprasegmental control. The cerebral hemispheres exert some influence, since signs of suprasegmental lesions may be detectable in the newborn, presumably while the lesion is acute, only to disappear in early months of infancy and reappear when normal functioning of the damaged areas should be evident.

**Postural Reflexes.** Afferent impulses for the *tonic neck reflex* originate in neck muscles. With the infant supine, turn the head sharply to one side. The arm and leg on the side to which the jaw is turned extend, or extensor tone increases; their fellows of the opposite side flex, or extensor tone decreases. In normal newborn infants these reflexes are incomplete, often more definite in leg than in arm; they tend to disappear during the first year, but partial responses may persist until the second or third year. Persistent asymmetry or complete and easy elicitation of the full response suggests a cerebral lesion.

Similar postural reflexes originate in the labyrinth (otolith righting reflex). Tilting the body of the erect infant while his eyes are covered induces a reflex righting movement

of the head, returning it to the erect position. When the head is turned, with the infant supine, the pelvis initially tilts opposite to head movement, then turns strongly in the other direction, the trunk thus following the head. Absence of this body righting reflex is an early sign of spasticity. In the *Landau reflex* the child is held prone, horizontally; head and neck extend, shoulders draw back and hips extend, the entire body forming a convex arc upward. Gentle pressure on the head or gravity flexes the neck, and legs and arms drop with it, reversing the arc. The same response may be seen when the normal child is learning to sit; he balances his head briefly, usually overextending slightly, then slumps forward with flexed neck and trunk, and arms dropping forward on the chest. When the spastic child attempts to sit, weakness of extension of trunk and neck forces him to slump forward, but pressure on the occiput produces overextension of neck and trunk, opisthotonos, exaggerated backward movement of shoulders and arms and extension of legs. The *Moro reflex* is a generalized extension and abduction of limbs and trunk followed by flexion and adduction; a sudden loud clap or slap on the table top elicits it. It is most valuable as an indication of general reflex irritability and normally disappears around four or five months of age.

**Placing and Stepping Reflexes.** Spontaneous limb movements of the newborn are either symmetrical or a part of quadrupedal progression. The prone newborn makes clear crawling movements; when held erect, with feet touching the table top and trunk inclined forward, he takes regularly alternating steps. If the dorsum of the foot is drawn against the under edge of the table top, the foot is lifted and placed atop the table. The infant, supported about the trunk, feet touching the table top, should be lifted suddenly up and down; this normally produces a supporting extensor thrust of the legs. Persistent extension or scissoring of the legs (*DeLange's sign*) is abnormal, as is asymmetry in any of these responses.

**Local Reflexes.** Myotatic reflexes are normally present, though extremely variable. Areflexia or persistent hyperactivity is abnormal; otherwise, only persistent asymmetry between the two sides is significant. The plantar response is usually extensor, and the grasp reflex present. Abdominal reflexes are generally present, though sluggish and perhaps with prolonged latency. Pupillary constriction and reflex closure of lids on exposure

to bright light and a corneal reflex are all demonstrable. Stroking the lips produces sucking (*sucking reflex*), and stimulating the side of the cheek close to the mouth causes the infant to turn his mouth and face toward the stimulus, the "*rooting*" reflex. Nystagmus on rotation and the Moro response to a loud sound indicate function of the lower levels of the vestibular and auditory system. The skin is sensitive to pinprick.

## EXAMINATION OF THE HYSTERICAL PATIENT

Malingering is rare in childhood, but hysterical symptoms are fairly common; only very young children are exempt. Organic symptoms may coexist with, or be perpetuated as, hysterical ones. The diagnosis of hysteria depends anamnesticly on demonstration of an appropriate emotional constitution and, almost always, a precipitating emotional crisis, sometimes clearly indicated by the kind of disability evoked. This portion of diagnosis, together with therapy, belongs in the domain of psychiatry. The role of the neurologist is to demonstrate the hysterical quality of the signs; he can best achieve this by physical examination without mechanical aids, hypnosis or narcosynthesis.

Hysterical symptoms, usually sudden in onset, tend to involve anatomic units or physiologic functions as a whole, and the victim shows a calm indifference inappropriate to his handicap. Common manifestations in childhood are (1) visual impairment or blindness, (2) paralysis of a limb or impairment of walking, (3) sensory loss or anesthesia, (4) loss of speech, (5) tremors or involuntary movements, (6) fits or disturbances of sensorium, (7) urinary retention.

*Visual defect* includes constriction of fields, amblyopia and amaurosis; hemianopsia and central scotomas are seldom if ever hysterical. Size of fields may change during perimetry, producing expanding, contracting or helical forms. If fixed in size, the field is very small and central and remains the same at whatever distance charted, a finding impossible for an organic constriction, owing to the divergence of the light rays subtended by the field. Impossible aberrations of color fields, e.g., red larger than blue, may be present. *Hysterical amblyopia* can generally be improved during examination by persuasion alone. In *hysterical amaurosis*, pupils and pupillary reflexes are normal and optokinetic nystagmus is present, establishing the

diagnosis. Photophobia, blepharospasm and convergence paralysis are common.

*Hysterical paralysis* may be paraplegic, monoplegic or hemiplegic. Normal reflexes and tone are preserved, and pathologic reflexes and the patterns of organic weakness are absent. The hemiparetic child may be tricked into movement by asking him to abduct or adduct both arms or both legs simultaneously; only conscious simulation will keep a normal limb from moving, palpable voluntary contraction then keeping it still. In *Hoover's test* the child elevates the normal leg strongly while the examiner keeps his hand beneath the heel of the paralyzed one; strong effort to raise the normal limb brings out downward pressure from a hysterically, but not an organically, paralyzed one. If partial movement is possible, the paretic limb regularly misses a mark set for it by about the same distance, whether a large or a small movement is required. Walking and standing are generally impaired together; both may be lost, though voluntary movement and coordination need not suffer (*astasia-abasia*).

*Ataxia* is usually greater in the trunk than in the limbs, and the stance is seldom wide-based; ataxia improves considerably if the child walks with two examiners ringing, but not touching, him with their arms.

*Tremors* are generally coarse, sometimes fairly rhythmic, but always reproducible by the examiner; they rarely cause difficulty in eating or dressing, except during observation.

*Hysterical sensory loss*, usually associated with paralysis, may be of glove or stocking type or involve a whole limb or one side of the body. It disregards neurologic boundaries and is usually absolute and to all modalities rather than incomplete or dissociated as in most organic illness. The level of sensory loss can be changed by shifting the point at which stimulation is begun; if one starts higher, the level is proportionately higher. Ask the child to close his eyes and say "Yes" when he feels a touch, "No" when he does not; hysterical children readily acquiesce and respond with "No" when the anesthetic area is touched. If one hand is involved, the Japanese illusion is useful; the child crosses his arms, palms opposed, clasps his fingers and brings the locked hands inward and upward. It is then very difficult for him to distinguish right from left; sensory stimulation or demand for movement produces gross inconsistencies.

*Hysterical aphonia* is seldom absolute; the child may not speak, but can whisper, sing or whistle; he may be mute with parents or

physician, but speak to his fellows. Normal movements of tongue, palate and vocal cords are preserved. *Hysterical fits* are distinguished from epileptic ones by absence of tongue biting, incontinence, cyanosis or pallor, change in pupillary reflexes, Babinski sign and incidental injuries. In the *stupors* or *catatonias* which may follow them the eyes are actively closed; Bell's phenomenon is present when the lids are forcibly opened, and pupils are normally reactive. *Urinary retention* is seen almost exclusively in girls; it does not alter the cystometrogram unless secondary infection has occurred.

## EXAMINATION OF THE UNCONSCIOUS PATIENT

This should include the following:

1. **Vital Signs.** Character of pulse and respirations, color and responsiveness to stimuli. Record these at beginning and end of the examination to secure a time-lapsed record and an estimate of changes due to stimulus of examination.

2. **Visuo-oculomotor System.** Position of eyes at rest, spontaneous movement and movement of eyes against passive movement of the head—a rough test for integrity of the vestibulo-ocular pathways. Note pupillary size, shape and reactivity to light and painful stimuli. Examine fundi carefully, but *do not dilate pupils*.

3. **Facial and Bulbar Functions.** Symmetry of movement of face on breathing and on painful supraorbital pressure, corneal reflexes, presence of spontaneous swallowing movements and gag reflex.

4. **Extremities.** Position at rest, the patient supine. Midbrain decerebration adducts, extends and internally rotates the arms, and extends and adducts the legs; tonic neck reflexes may appear spontaneously or be induced by turning the head. Note spontaneous and induced movements of limbs; hemiparetic limbs move less under both circumstances than normal ones; the leg in hemiplegia rotates externally at the hip, the oval outline of the thigh is transverse rather than vertical, and the foot points downward and outward. Raise the arms together and allow them to fall—a hemiplegic one falls more quickly and with less minor movements of adjustment than a normal one. Draw the legs up, knees flexed and soles flat, then release them suddenly—a hemiplegic leg falls outward, and the foot slips down on the sheet faster than a normal one. Check myotatic

reflexes, which may be absent in recent hemiplegia, spinal shock or deep coma; asymmetries are more significant than generalized changes.

5. **Sensation.** Stimulate fairly vigorously with a pin, especially on soles of feet and on hands. Cross the midline of the trunk and ascend either side with a series of pinpricks. Sensory impairment may be detected by a sudden twitch or an incomplete protective movement when one crosses from hyperesthetic to normally innervated skin.

6. **Trophic and Circulatory Changes.** Note color, mottling and temperature of the skin. Fresh hemiplegias or transverse cord lesions cause warmth of the affected limbs from vasodilations. Palpate carefully for distended bladder.

7. **Miscellaneous Signs.** Meningisms, bruises, rashes, fractures, and odor of breath.

## SPECIAL DIAGNOSTIC PROCEDURES

Special studies may be desirable for the information they provide and for the reason that abnormality demonstrated by a mechanical procedure often seems more comprehensible to the parent than that resting on clinical opinion. Some are harmless; others entail real hazard, which must be weighed carefully against the potential value of the information they may provide.

Such special studies include (1) lumbar puncture, (2) subdural and ventricular punctures, (3) radiologic studies (plain films, pneumoencephalography, ventriculography, angiography, isotope scanning and myelography), (4) electroencephalography, (5) psychologic and psychometric studies, and (6) biopsy.

**Lumbar Puncture.** Carelessness and failure to pay attention to essential details often negate the potential value of the lumbar puncture. Contraindications are increased intracranial pressure due to space-taking lesions, local sepsis in the lumbar region and a bleeding tendency. The equipment consists of no. 19 and 20 lumbar puncture needles, 1½, 2 and 2½ inches in length, well sharpened, short-bevelled and with smoothly fitting stylets, an Ayer type of glass manometer, procaine, hypodermic needles and syringes, a three-way stopcock, collection tubes and the usual equipment for a minor, sterile procedure. Older children usually cooperate, younger ones need to be held; sedation is desirable, but volatile anesthetics should be avoided, since many raise intracranial pres-

sure. The child lies with his back, widely "prepped," absolutely vertical to the table, and knees, hips and neck flexed as little as necessary. A procaine infiltration is worth while, even in infants. The needle is introduced absolutely in the mid-sagittal plane of the child's body, at the third, fourth or fifth lumbar interspace, its point slightly cephalad; it is advanced slowly, the stylet repeatedly withdrawn, until cerebrospinal fluid drips out. This slow approach avoids passing entirely through the theca. When fluid is dripping, the stopcock and manometer are attached, and the child is encouraged to relax by every reassurance and entertainment possible; a proper approach can accomplish much, even with infants. A resting pressure is recorded as soon as the fluid column stabilizes, oscillating freely. Jugular and abdominal compression is done, if indicated, and appropriate quantities of cerebrospinal fluid removed stepwise, in 1-cc. aliquots; the closing pressure is recorded, the needle removed, its track broken by firm massage with the finger, and a small dry sterile dressing placed over the site. Bed rest after the procedure is unnecessary, since postpuncture headache is rare in children; occasionally, stiff back and headache, with persistent low cerebrospinal fluid pressure, occur; these complications appear unrelated to technical errors of the procedure.

Proper examination of the cerebrospinal fluid is of great importance in differential diagnosis of central nervous system disease, though the values determined are few. One wishes to know (1) pressure, and freedom of oscillation; (2) color; (3) cellular constituents; (4) protein; (5) glucose and rarely chloride; (6) evidence for infection.

**Pressure** normally varies from about 60 to 180 mm. of fluid if the child is really relaxed; the mean is about 120 mm., pressures in infancy being somewhat lower. Pressure must be read from a manometer; estimation by speed of flow is completely inaccurate. Compression of the abdomen raises cerebrospinal fluid pressure by about 10 to 20 per cent by raising the pressure in epidural veins and compressing the theca; pressure on the jugular vein raises cerebrospinal fluid pressure by 30 to 50 per cent by increasing the intracranial vascular compartment; if a block exists in the spinal theca, abdominal compression is effective, but jugular compression ineffective, in causing these rises, since intracranial changes cannot be communicated to the lumbar theca. Jugular compression in the face of increased intracranial pressure can be

dangerous by causing or worsening a cerebral hernia.

**Color.** Normal cerebrospinal fluid is as clear and colorless as distilled water; it should be compared to a tube of distilled water, held against a white background. High increase in protein gives a faint opalescence to a definite yellow tint; old hemorrhage produces definite xanthochromia, leukocytes above a hundred or so casual turbidity, and fresh blood, opalescence to pinkness or outright bloodiness. The bloody tap tends to clear on removal of successive quantities of fluid, xanthochromia after centrifugation is absent, and the proportions of erythrocytes to leukocytes is that of the child's peripheral blood; a differential count of red and white cells in the fluid, and an immediate red and white cell count on peripheral blood, must be done if blood from a traumatic tap is to be distinguished from endogenous blood.

**Cells.** The cerebrospinal fluid normally contains less than 5 leukocytes per cubic millimeter. More than 5 white blood cells, and polymorphonuclear or red cells in any number, are abnormal. Cells must be counted within thirty minutes, since sedimentation or breakdown soon occurs.

**Protein.** This varies with the location of the source of the fluid and with different laboratory methods. Ventricular fluid contains 15 mg. total protein per 100 ml. or less, cisternal fluid about the same or a trifle more, and lumbar fluid 15 to 40 mg. For a quick estimate, one drop of cerebrospinal fluid is dropped into 1 cc. of 5 per cent aqueous phenol (Pandy's fluid) and observed without shaking. A clouding or precipitate at the interface usually represents increased protein content, the test being much more sensitive for globulin than for albumin. The fluids must be at the same temperature, since chilled Pandy's reagent will produce a faint clouding. A quantitative total protein determination should always be obtained.

**Glucose.** This normally is about one half to two thirds of the blood sugar. The glucose level of the blood should be determined at the time of lumbar puncture.

**Evidence of infection.** Serologic tests for syphilis, colloidal gold or colloidal mastic and sometimes Treponema immobilization tests should be obtained when indicated. A cellular fluid should always be cultured for bacteria at the time of puncture and on warmed media; if meningitis is a possibility, even an acellular fluid should be cultured. Cultures for fungi and acid-fast bacilli should be obtained when

indicated. All cellular fluids should be centrifuged, and a stained smear should be examined for a differential count of cells and for organisms.

The cerebrospinal fluid of infants in the first few days or weeks of life is often xanthochromic, with protein as high as 80 to 100 mg. per 100 ml., and often has an excess of red and white blood cells. These findings, though not normal, are usually an expression of intracranial complications of birth, such as venous congestion or minor trauma, often without other symptoms or recognized residuals.

**Cisternal Puncture.** The only indication for cisternal puncture is unavailability of the lumbar route. Possible cerebellar herniation or the Arnold-Chiari defect is a contraindication. The child is placed so that his head rests evenly on one side or in the sitting position with his chin flexed on his chest. The spine of the axis is located, and a line joining the external auditory canal and glabella is determined. The needle is introduced immediately above the axial spine in the midline, inclining slightly upward from the auditory-glabellar plane until it touches the occipital bone; the approximate depth is noted, the needle is then withdrawn to the skin, but not through it, and reintroduced in planes successively closer to the auditory-glabellar one with the stylet withdrawn repeatedly until fluid drips out or the needle strikes the occiput again. The depth of the cistern from the surface varies from about 1.5 cm. in infants to 3 to 4 cm. in adults. The danger of fatal injury to the medulla or of hemorrhage is real, and the procedure should not be attempted for the first time on a live child.

**Subdural and Ventricular Punctures.** These important diagnostic procedures are carried out only on infants whose sutures are open. The equipment is that for lumbar puncture. The child is entertained with a sugar or brandy nipple, his head shaved at least to the bregma or, better, entirely. A wide sterile preparation is made over the vault, and the head draped with a "posterior drape" towel. The lateral angle of the anterior fontanel is palpated, and a procaine skin wheal raised. A short lumbar puncture needle is then introduced, perpendicular to the scalp surface, not less than 1 to 1½ inches lateral to the midline, firmly supported and not allowed to wobble. Scalp and skull once penetrated, the stylet is withdrawn. If subdural fluid is present, it usually drips out at once. More than

1 ml. of fluid, or fluid discolored by anything other than proved fresh blood, is abnormal. If fluid is not encountered, the needle is passed inward about 1.5 cm., then withdrawn slowly, since occasionally membrane or outer clot of a hematoma may occlude it. Cell count, color estimation, protein and culture are secured on any fluid obtained; both sides should be tapped, since four fifths of infantile subdural hematomas are bilateral. No more than 10 to 15 ml. of fluid should be removed at any time from either side, nor more than a total of 20 to 25 ml.; removal of 30 ml. or more may cause sudden intracranial decompression and shock. A sterile dressing is applied, and the track of this puncture avoided in succeeding ones.

Puncture of ventricles is accomplished in the same manner, except that the needle point is inclined forward toward the root of the patient's nose. If freely entered, the ventricles are almost always enlarged. Phenolsulphonphthalein, 1 cc., or Evans blue, 1 cc., may be injected, and patency of the foramina of Monro demonstrated by its recovery from the other ventricle; this is not always reliable, since fenestrae are sometimes present in the septum pellucidum. Rapid recovery of dye from the lumbar theca indicates a patent ventricular system; failure to appear in more than twenty minutes almost always means midline obstruction of the ventricular system or spinal block.

**Radiologic Studies.** 1. *Plain films.* These should always precede any special radiologic study. Views of the skull, anteroposterior, postero-anterior, lateral and basal views are adequate for most neurologic studies. Films of the vertebral column in spinal cord disease, of the optic foramina, of bones and joints in metabolic disease and of the chest and abdomen may be indicated.

2. *Pneumoencephalography.* In this procedure air or other gas such as helium or oxygen is introduced into the subarachnoid space, usually in the lumbar region, sometimes by cisternal puncture. By proper positioning ventricles and/or subarachnoid spaces may be filled. The procedure usually requires general anesthesia; in so-called total replacement large volumes of cerebrospinal fluid (80 to 120 cc.) are replaced by air; in fractional replacement only 25 to 40 cc. of air are used. The former gives more complete filling, especially in the hands of the less skilled operator; the latter is more time-consuming and requires more skill and care in introducing the air and positioning the

head and more of the radiologist's time. It is a much less severe procedure for the patient and better adapted to deliberate filling of specific parts of ventricular or subarachnoid systems. When time and personnel permit, it is to be preferred.

Pneumoencephalography can be dangerous; the mortality rate attributable to the procedure is 0.2 to 0.3 per cent, usually in patients with a mass lesion; it is higher in young children and when too much air is used. Most patients have headache, irritability, fever and vomiting for a day or more afterward. Air accidentally entering the subdural space may cause subdural hematoma. The procedure causes pleocytosis and increased protein in the cerebrospinal fluid, sometimes with meningeal signs; cerebrospinal fluid studies should always precede it.

The pneumoencephalogram demonstrates shape, size, symmetry and position of the ventricular system and subarachnoid spaces. Its greatest value is in visualizing localized static defects, atrophies and congenital malformations. A film taken twelve or twenty-four hours after the procedure may show porencephalic cysts and similar defects more clearly than the original films.

3. *Ventriculography.* When there is reasonable possibility of an expanding lesion or of increased intracranial pressure, ventriculography should be used. Here the gas is put directly into the ventricular system, through the patent fontanel of the infant or burr holes in the older child. The mortality rate of the procedure is almost impossible to calculate, since the subjects often are seriously ill; it can be the direct cause of death in patients with high intracranial pressure by causing hemorrhage from subependymal veins. Visualization of the fourth ventricle and of the subarachnoid spaces is less satisfactory than with the pneumoencephalogram.

4. *Angiography.* A radiopaque substance, usually Diodrast or Hypaque, is injected into a carotid or vertebral artery or into a dural sinus. General anesthesia and, especially in smaller children, surgical exposure of the vessel to be injected may be necessary. Angiography is the procedure of election for vascular anomalies and vascular lesions; it is also of value in localization of tumors, especially in the cerebral hemispheres. It is not without danger. Hemiplegias, usually transient, occur in as many as 4 per cent of cases. Convulsions, petechiae, transient loss of vision, occlusion of retinal arteries, throm-

bosis of the artery at the site of puncture, hematoma of the neck requiring tracheotomy and even sudden death have all been reported. For the delineation of vascular lesions the procedure is indispensable; for space-taking lesions its great advantage over gas-contrast studies is that it does not demand immediate operation if a mass is demonstrated.

5. *Isotope scanning procedures.* The use of scintillometer scanning of the head after injection of a short half-life isotope which concentrates in tumor tissue, such as RIHSA (radioactive iodized human serum albumin), is becoming common. Supratentorial masses seem to be demonstrated better than infratentorial ones. Its possibilities and limitations are not yet clear, but it is certainly much less traumatic and potentially less dangerous than any of the other radiologic methods used to locate tumors.

6. *Myelography.* Contrast radiography is also used in the localization of intraspinal masses; the common contrast medium is Pantopaque. Three to 6 ml. or more are introduced within the theca, either in the lumbar region or cisternally, and the flow of dye and irregularity or obstruction to the column observed fluoroscopically and on spot films taken on the tilting table. The dye should be removed, the reason being principally medicolegal.

The procedure is not especially dangerous, though in a few instances transverse myelitis, severe lesions of the cauda equina or obliterative arachnoiditis have seemed to follow it; if dye enters the cranium, a fatal progressive obstructive hydrocephalus may ensue. Such accidents are thought to be due to contamination of equipment or dye with detergents or disinfectant solutions. The procedure regularly causes a pleocytosis and an increase in cerebrospinal protein, and often a mild fever for a day or so.

*Electroencephalography* (see also p. 1120). This procedure, having the advantage of being harmless and repeatable, can be given too great weight in neurologic diagnosis. It is of value in establishing the presence of a central nervous system abnormality, and of assistance in the diagnosis of epilepsy, though the electroencephalogram alone is seldom the determining diagnostic factor. It sometimes localizes expanding lesions, but its accuracy is only about 60 per cent; it has prognostic value in following the course of encephalitis, encephalopathy or head injury. A great limiting factor is the variability of interpretation

put on the same tracing by different observers. One should not commit himself irrevocably to a diagnosis whose sole support is an electroencephalogram.

**Psychologic Studies.** These are of great value. A carefully performed intelligence quotient test often resolves the difficult differentiation of mental retardation from emotional disturbance. Too frequent repetition should be avoided, and the clinician should remember that such evaluations are not absolute measurements.

**Biopsy.** Muscle biopsy is quite innocuous

and often indispensable in differentiating myopathic wasting from neural atrophy; a muscle showing clear, but not the most extreme, degree of involvement should be selected and a wedge of skin always included. Biopsy of brain is indicated when a definitive diagnosis of a degenerative disease becomes imperative for reasons of genetic counseling or overpowering family emotional stress. The right temporal tip or a wedge of cerebellum is removed through a small craniotomy; punch or needle biopsies are dangerous and usually histologically worthless.

## SYMPTOMATOLOGY OF NEUROLOGIC DISEASE IN CHILDHOOD

*Visual loss* in infancy usually impairs optic fixation and the conjugate movements of the eyes. Failure to focus or wandering movements of the eyes are the complaint; in later childhood these changes suggest early visual loss. In older children the holding of objects close to the eyes and the mistaking of colors are the common symptoms. Poor vision in one eye, unless the eye deviates and strabismus develops, often goes unsuspected until a chance test of acuity reveals it. Vision may blur and fail from diplopia before strabismus is apparent. The child then tilts his head into positions in which diplopia is less, usually turning the face in the direction of the weak muscle, so that binocular vision is attained for objects directly ahead without use of the weak muscle. Head-tilting in association with a posterior fossa tumor may not be ocular in origin, but due to tonsillar herniation, meningeal irritation or stiff neck; the head then usually turns toward the side of the lesion.

Right vertical halves of visual fields represent left vertical halves of retinas, left optic tract and visual centers, and vice versa. Vertical defects are termed *hemianopsias*. *Homonymous defects* involve either the right or the left halves of the visual fields, and are caused by retrochiasmatic lesions. *Heteronymous hemianopsia* is almost always bitemporal and is due to pressure on optic fibers decussating in the chiasm. Since fibers of the papillomacular bundle are more sensitive to pressure and toxins than the remainder of the nerve, early chiasmatic compression and toxic states may cause central scotomas.

*Hemianopsias* lead to persistent ignoring or bumping into objects on one side and can be confused with lateralized cerebellar lesions, in which the child may constantly deviate to the side of his lesion. The child with tubular vision or a bitemporal hemianopsia attends only to objects directly ahead. Cortical blindness is almost always accompanied by mental change or other signs of cortical deficit.

*Impaired hearing* (p. 766) has two major symptoms. The first is inattention to sounds unless they are very loud or productive of vibrations transmissible through the body; the child will not react to a call when his back is turned, but will turn if one stamps on the floor. The second, appearing with hearing loss in early childhood, is failure of development of normal speech; in such cases hearing loss must be differentiated from mental retardation.

*Vertiginous children*, especially young ones, are unwilling to move; they wedge themselves, face down and eyes closed, in a corner of the crib or playpen.

*Organic headache* is due to distention and deformation of pain-sensitive blood vessels and meninges. Meninges of the supratentorial region are supplied by the trigeminal nerve, those of the posterior fossa by upper cervical roots and the vagus. The pain from supratentorial lesions is usually bifrontal, that from infratentorial irritation, suboccipital. Organic headache is dull, throbbing or bursting; functional headache more commonly is manifest by a feeling of pressure. Though

subjective descriptions are of less value in children than in adults, a headache lavishly described is usually not organic.

In young children the presence of headache is inferred from fretfulness and irritability, furrowed brow and sometimes ear-pulling or head-rolling. In older children the pattern of the headache is most important. Headache of increased intracranial pressure accompanies change of position, such as rising in the morning, stooping, straining or exercising; at first it is not constant; when it becomes so, lethargy and drowsiness usually accompany it. Vascular headache, common in cyanotic heart disease, is due to increased cerebral oxygen demand and distention of blood vessels; it is regularly caused by activity and relieved by rest. The distinctive feature of *migraine* is the episodic, periodic, repetitive pattern of attacks. Prodromes and auras usually go unnoticed, though the mother may comment on a period of quiet before the child complains of headache and photophobia, becomes listless and, after an hour or so, is nauseated or vomits; vomiting relieves the headache, and after deep sleep the child awakens feeling as well as ever. Neurotic headache lasts for indefinite periods and fluctuates in relation to surrounding events; the child can often be distracted from his pain. Vomiting as a neurologic symptom is distinctive only when it becomes projectile with severely increased intracranial pressure.

With *cerebellar lesions* unsteady gait is usually the first recognized symptom. Ataxia of the extremities, such as impaired manual dexterity in writing, awkward steps or rarely slurred ataxic speech is noted later. Alert parents may note dysmetria, a tendency to overshoot or undershoot when reaching for objects, or decomposition of movements, each movement being broken into a series of lesser ones to control ataxia. Hypotonia reduces associated movement; thus an affected arm hangs limp and motionless as the child walks.

Nystagmus, the only ocular symptom of cerebellar disease per se, is noted by parents only if extreme and by children as blurring or dancing of objects. Expanding cerebellar lesions rarely cause spontaneous nystagmus, and then only in conjunction with a conjugate deviation. The nystagmus is slow and coarse when looking to the side of a lesion, fine and rapid when looking away from it. Skew deviations, the homolateral eye deviating downward and inward and the opposite one upward and outward, signify acute le-

sions. Vertigo or giddiness makes the young child unwilling to move, but it may be mentioned spontaneously by the older one.

*Lesions in the brain stem* produce cranial nerve palsies early. Involvement of long motor pathways is more apparent than that of sensory ones and causes unsteady gait; sphincters are spared until late. Medullary lesions cause vomiting without increased intracranial pressure; mesencephalic ones combine hemiplegia or tremor with oculomotor palsy. Interference with the reticular systems disturbs consciousness. This may vary from deep coma with bradycardia, bradypnea and hypertension in lower-placed lesions to states of akinetic mutism, in which the patient appears awake, but does not speak or respond, or to simple hypersomnolence in upper brain stem or thalamic lesions.

*Disorders of the cerebral hemispheres* produce a variety of motor symptoms. Hemiparesis, if cortical, is usually flaccid; if the deeper white matter or basal ganglia are involved, spasticity, rigidity or choreo-athetosis appears. The first symptom of motor impairment is disuse of affected limbs. In congenital lesions disuse of the paretic hand causes apparent precocious handedness with the opposite member; when the child walks, he drags or circumducts the paretic leg. The older child uses the affected hand clumsily, shifts his handedness or limps. Growth arrest characterizes congenital or slowly progressive hemiparesis, especially if the lesion is parietal. Apraxia impresses parents only as clumsiness.

Sensory loss with cerebral lesions is almost always dissociated. For example, discrimination of shape and texture and of two-point tactile stimulation suffers more than general cutaneous sensibility. The latter is reduced rather than lost, and the deficit is seldom mentioned. Simultaneous bilateral stimulation may reveal an otherwise unnoticed sensory loss, the child disregarding stimuli on the involved side. Specific sensory disorders, notably hemianopsias, and sensorimotor dysfunctions, particularly aphasias, may be present and aid in localization. Mental changes in the young child usually cause hyperirritability first, less frequently lethargy. Older children become more emotionally labile and lose their powers of concentration and do poorly at school; lethargy and general restriction of interest come later. Seizures, the commonest symptom of discharging lesions, for practical purposes limit the lesion to the cerebral hemispheres; they may be of any sort.

## STATIC AND DEVELOPMENTAL LESIONS

About two thirds of neurologic disease in childhood is caused by lesions which are themselves static. The clinical manifestations progress only as structural and functional maturation of the nervous system is altered and secondary complications, such as hydrocephalus or repeated seizures, may further damage the brain or cord. These lesions result from various sorts of antenatal, perinatal or postnatal injuries to the developing nervous system.

**Etiology.** In the antenatal period the time and nature of the injury, together with genetic and environmental factors, affect the fetus (see p. 242). Similar injuries may cause different maldevelopments; conversely, widely differing agents may produce identical defects. *Antenatally*, genetic factors, hormonal or dietary disturbances, placental disease, maternal toxemia, age and parity of mother, age of father, intrauterine infection and hypoxia, toxic agents or radiation may all be factors. *Perinatally acquired lesions* are due principally to prematurity, hypoxia, trauma, hemorrhage, toxic states and infections. *Postnatal lesions* are mainly sequels of infections, trauma, metabolic disturbances such as hyperelectrolytemia and hypoglycemia, and vascular disease.

The *incidence* of such static lesions is difficult to estimate, since accuracy of diagnosis and reporting vary tremendously. Further, the problem is one of continuous reproductive wastage; the loss due to abortion and stillbirth is seldom included. About 6 per cent of all children at some time require special management for organic or functional illness referable to the central nervous system; about 1 per cent are handicapped by a static lesion of the brain.

**Clinical Features and Pathology.** Antenatal defects are often called maldevelopments. Many represent either failure of closure or cleftlike arrests of the neural tube.

In *anencephaly* the trunk and limbs are normally formed, but the neck is short. The brain is represented by a vascular mass in which optic nerves end blindly; the condition is incompatible with maintained extrauterine life.

*True porencephaly* is a defect (cavity or cyst) of the cerebral hemisphere, often bilateral and close to the midline; it extends

from the ventricle to the pia, without entering the subarachnoid space. It is distinguished from *false porencephaly*, single or multiple cavities which do not communicate with the ventricles and are caused by vascular damage at birth. Symptoms are hemiplegias, seizures or mental retardation.

*Arrhinencephaly* is an arrest of development of the forebrain, particularly the olfactory portions; the brain consists of a solid mass anteriorly with a single ventricle or cyst posteriorly. The children are spastic and profoundly retarded.

*Agenesis of the corpus callosum* (Fig. 314) combines partial or complete absence of the corpus callosum with microgyria, porencephaly or heterotopias. Hydrocephalus is usually present, and lipomas or meningiomas sometimes develop in the defect. Many patients are mentally defective, not from the callosal defect, but because of associated abnormalities. Mental and motor retardation, hydrocephalus, spasticity and sometimes seizures are the usual manifestations.

In the posterior fossa three major defects occur.

FIG. 314. Agenesis of the corpus callosum. Ventricles are dilated, and the lateral ventricles widely separated.

FIG. 315. Thoracolumbar meningocele, Arnold-Chiari defect and intrauterine hydrocephalus.

*Atresia of the aqueduct of Sylvius* is a congenital narrowing of the upper portion of the channel, which is sometimes forked or obstructed by a transverse septum. Secondary stenosis may follow ependymitis, intraventricular hemorrhage or birth trauma. Other developmental defects coexist. Symptomatically, the stricture causes obstructive hydrocephalus, the posterior fossa remaining shallow.

The *Arnold-Chiari deformity* is a tongue-like projection of the cerebellum and choroid plexus extending with an elongated fourth ventricle into the cervical canal; the upper cervical spinal cord is kinked backward, and the cerebellar tonsils are drawn into and are adherent to the foramen magnum. Lumbosacral spina bifida and myelodysplasia are present in about half the cases, and at times there are aqueductal stenosis and heterotopias. The defect appears between the sixteenth and twentieth fetal weeks and seems to be due to local overgrowth of the neural tube rather than to fixation and traction on the neuraxis by myelodysplasia. It causes obstructive hydrocephalus.

In *atresia of the foramina of Luschka and Magendie* (Dandy-Walker deformity) the fourth ventricle is ballooned out into a large cavity, above which lie the cerebellar vermis, the elevated lateral sinus and the torcular Herophili. Hydrocephalus is the common

manifestation; demonstration of the elevated torcular by roentgenogram or sinography or, in the infant, simply by transillumination, establishes the diagnosis.

In the spinal cord, defects are most frequent in the lumbosacral region, but may be cervical or thoracic. They include asymptomatic *spina bifida occulta* and *spina bifida with an associated lipoma or dermoid* or with a *meningocele* or *meningomyelocele*, a sac containing malformed cord and roots and covered by a thin, vascular membrane; the trunk and limbs below the level of the deformity are paralyzed, often underdeveloped and anesthetic, and bowel and bladder sphincters are nonfunctional (Fig. 315). *Dysrhapism* is a duplication of parts or all of the cord. Complete duplication is *diplomyelia*; incomplete duplication, usually accompanied by vertebral defects and an osseous spur extending upward from the vertebral body separating the duplicated cords, constitutes *diastematomyelia*.

*Congenital dermal sinuses* are persistent, epithelium-lined defects extending from the skin toward or into neural structures. The pilonidal sinus in the sacral area is the most common one, but they may be found anywhere along the vertebral column or in the occipital or frontal regions of the skull. Externally, a tiny pore is surrounded by hair or a port-wine mark, and it may exude a whitish secretion.

Skull growth is in large part dependent on brain growth, and arrest of it can result in *microcephaly*; the head reaches a maximal circumference of 42.0 cm.; the brain is agyric or microgyric and weighs less than 1000 gm. Secondary microcephaly occurs after a variety of injuries and is usually accompanied by neurologic manifestations. A rare variety is familial, in which the involved persons may show surprisingly few evidences other than generalized hypertonus. Severe mental retardation is present in both groups.

True *megalecephalon* is rare, most large heads being due to hydrocephalus or space-taking lesions. In adult life the megalencephalic brain usually weighs 2000 gm. or more. The cortical gray matter is increased in amount; heterotopias and developmental defects are frequent; neurons are poorly differentiated, and glial cells increased in number. A few cases are associated with adrenal abnormalities and with tuberous sclerosis. The patients are mentally retarded, usually epileptic and occasionally spastic. Pneumograms are necessary to distinguish megalen-

cephalon from hydrocephalus, space-occupying lesions or, rarely, diffuse granulomatous or parasitic lesions.

The brains of many congenitally defective persons are not grossly or obviously deformed, but only small, with simple or irregular convolitional patterns, poor lamination of the cortex, immature nerve cells and defective myelination; the term *oligocephalon* has been applied. The patients themselves are moderately defective, their genetic backgrounds often complicated by mental deficiency and emotional instability. Neurologic manifestations are usually absent or slight.

Brain injury of the *perinatal period* is due principally to metabolic and toxic disorders, trauma, hemorrhage and infections; vulnerability is accentuated by premature birth.

The commonest and most important metabolic disorder is *inadequate oxygenation*. Hypoxia is a part of almost all forms of birth injury to the brain (p. 321). Hypoglycemia, especially in infants of diabetic mothers, is another metabolic cause.

The most important toxic state damaging the newborn brain is *hyperbilirubinemia*, which produces the syndrome of *kernicterus* (see pp. 334 and 958). In this condition excess bilirubin of the indirect type accumulates in the blood, owing either to overproduction or perhaps to defects of conjugation with glucuronic acid; incompatibilities of blood type, immaturity of mechanisms of conjugation and excretion, neonatal sepsis and therapy with sulfisoxazole in the premature infant and excess administration of vitamin K are known causes. Permeability of the blood-brain barrier in the first few days of life permits bilirubin to reach nerve cells, which it damages probably by inhibiting intracellular enzyme systems. Certain regions, particularly the corpus subthalamicum, hippocampus, striate bodies, thalamus, inferior olives, cerebellar nuclei and cranial nerve nuclei are stained intensely yellow. This selectivity may depend on attainment of a specific state of maturation of neuronal enzyme systems; at any rate the cells involved are all large and phylogenetically old. Nonpigmented areas may also be damaged. Loss of neurons, reactive gliosis and atrophy of involved fiber systems are late findings.

The clinical features of kernicterus are constant and usually appear from the second to the sixth day of life. Minimal cerebral damage may not be apparent at this time. Usually the infant either appears gravely ill, prostrated, with diminished Moro and tendon

reflexes, failure to suck and respiratory distress, or he becomes opisthotonic, with bulging fontanel, twitching of face or limbs and convulsions. Rarely is there rigidity or involuntary movements. Many such infants die; the remainder, usually seriously damaged, appear to recover and for two or three months manifest few abnormalities. In later months of the first year of life, opisthotonos and muscular rigidity return and irregular movements and convulsions occur. In the second year opisthotonos and seizures abate, but involuntary movements, muscular rigidity and, in some infants, hypotonia increase steadily. By three years of age the complete neurologic syndrome is apparent. About 80 per cent of affected children have bilateral choreo-athetosis with involuntary mobile spasm. Pyramidal signs are rare in proportion to extrapyramidal ones, and hypotonia and ataxia distinguish a few. Seizures, mental deficiency, explosive dysarthric speech, high tone hearing loss, squints and defective upward movement of the eyes are common. It is possible that Rh incompatibility without neonatal jaundice may result in hearing loss, mental limitation and learning disorders, though the relationship is not proved.

*Prematurity* (p. 306) may be an expression or a cause of brain abnormality. At least one fifth of prematurely born infants later show signs of cerebral involvement. Some of this results from birth injury to the soft premature skull, hyperbilirubinemia, intraventricular hemorrhage or hypoxia, but the possibility of antenatal defects always exists.

*Trauma* (see also p. 315) of the perinatal period affects the brain more by deforming the skull and its contents than by impact force. Molding of the head and overriding of sutures tear small veins, sinuses or the tentorium, producing subarachnoid or subdural bleeding; large veins, sinuses or major arteries may be compressed and venous stasis or areas of hypoxia produced. Direct compression of the skull by forceps or ischial spines can cause local ischemia or vascular damage.

*Hemorrhage* is a less common primary source of damage than was formerly thought; microscopic hemorrhage and slight xanthochromia of cerebrospinal fluid occur in perhaps one fifth of all newborn infants, but per se are not evidence of significant brain injury. Gross hemorrhage is now rare, but smaller petechial or perivascular hemorrhage following vascular compression or hypoxic damage to endothelium is common. Intra-

FIG. 316. Calcified ependymitis and hydrocephalus following cytomegalic inclusion body disease in the newborn.

ventricular hemorrhage, immediate or delayed, from the terminal veins is frequent in small premature infants (p. 316).

*Infections* include both intrauterine and neonatal encephalitis and complications of neonatal sepsis. Toxoplasmosis (p. 615) and cytomegalic inclusion body disease (p. 524) produce a severe encephalitis, the lesions of which may be calcified at birth (Fig. 316). Neonatal sepsis may cause hyperbilirubinemia, meningitis, venous or sinus thrombosis or toxemias severe enough to damage the brain.

It is still difficult to relate any particular form of abnormal birth to any constant form of brain injury. Difficult labors with pallid asphyxia of the newborn seem associated with severe damage to the basal ganglia and thalamus (Fig. 317); a peculiar marbled appearance, called *status marmoratus*, is found in the basal ganglia, thalamus and sometimes the cortex. Clinically there usually are combined pyramidal and extrapyramidal syndromes and mental retardation. Venous stasis, compression of the galenic vein and perhaps sudden fluctuations in intracranial pressure, when the head is delivered through a contracted pelvis or rapidly in breech delivery, may result in cystic degeneration of the white matter. Spastic diplegia is the usual result. Other than this, prediction of types of clinical abnormalities or of pathologic le-

sions of abnormalities recognized at birth can seldom be made.

*Postnatal lesions* are sequels of infections, principally meningitis and encephalitis, injuries, subdural hematomas, metabolic disturbances such as hyperelectrolytemia or embolic and inflammatory cerebral vascular disease. Their etiology is usually clearer than that of prenatal or perinatal lesions, the principal exception being the infant or young child, previously said to be well, who begins to have seizures, goes into status epilepticus and is left with definite signs of cerebral injury. It is often impossible to tell whether the seizures, hypoxia and perhaps hypoglycemia injured the brain, or whether they further damaged a brain of whose abnormal-

FIG. 317. Cerebral birth injuries. A, Focus of softening in internal capsule in a prematurely born spastic child. B, Necrosis of cells in the lateral thalamic nucleus in a severely molded head.

ity they were the first recognized manifestations.

**Treatment.** Prevention of static lesions is obviously the desired goal. This demands far greater knowledge of etiology and pathogenesis than is presently available (see p. 293).

Some static lesions can be treated surgically. Aqueductal atresia, the Dandy-Walker or Arnold-Chiari defects all produce obstructive hydrocephalus and are so managed (p. 1092). Simple cranium bifidum requires no treatment, but cranial meningocele or meningoencephalocele should be repaired by amputation of the sac and repair within the skull. Congenital dermal sinuses should be excised in toto as soon as discovered, since they offer a portal of entry for infection and entail constant risk of meningitis or brain abscess. Diastematomyelia and spinal meningocele, with or without lipoma or dermoid, are better left alone, unless they are producing increasing disorders of gait or sphincter control.

*Myelodysplasia (spina bifida with meningocele)* offers one of the most serious problems. Operation can remove the sac, close the skin defect and lessen the nursing problem, but it does not improve the neurologic deficit. A life of paraplegia and incontinence, ending in the second or third decade with pyelonephritis and uremia, is the usual pattern. Since the Arnold-Chiari defect, aqueductal atresia, or both, are present in more than half the cases of myelodysplasia, obstructive hydrocephalus frequently develops, and early operation is blamed for its appearance. Good results cannot be expected from sur-

gery in infants with (1) severe paralysis of the legs, (2) fecal and urinary incontinence, (3) hydrocephalus, (4) severe mental retardation, or (5) multiple congenital defects. With such infants the sac and skin should be kept clean with dry dressings, and excoriation of the perineum and buttocks should be avoided by careful hygiene and exposure to air and sunlight. If hydrocephalus does not appear and mental development seems normal, repair may be done some months later. When the paralysis is incomplete, and there is no evidence of incontinence or hydrocephalus, the lesion is usually repaired at once. Results, even with orthopedic assistance, physiotherapy, efforts at bowel and bladder training, fluid restriction and low residue diets, are seldom very good.

Perinatal and postnatal static lesions are seldom treated surgically. If hydrocephalus appears, it is usually early, and the prognosis for surgical improvement is poor. Resection of scarred or atrophic areas or even hemispherectomy occasionally relieves otherwise intractable seizures, but should be considered only after intensive medical therapy has failed. Destructive operations on the brain or cord to relieve tremor, involuntary movements or spasticity to date have given few good results.

Most children with static lesions of the brain or cord present a variety of problems: mental limitation, neuromuscular handicaps, seizures, learning difficulties and problems of emotional and social adjustment. These are discussed in the treatment of the cerebral palsied child (p. 1141).

## ECTODERMAL DYSPLASIAS

These hereditary conditions, also known as phakomatoses, combine congenital lesions of the skin and nervous system with a wide variety of visceral and somatic abnormalities. Often inapparent at birth, they may appear as mixed and incomplete syndromes.

*Tuberous sclerosis* is inherited as a dominant trait. The widespread lesions include those (1) of the *skin*, fibroadenomas of sebaceous glands over the nose and cheeks (butterfly area), "shagreen" or leathery patches, *café-au-lait* and depigmented spots and subungual fibromas; (2) in the *viscera*, hemangiomas or mixed tumors of kidney, liver and spleen, multiple tiny mixed tumors

of the lung associated with spontaneous pneumothorax, and rhabdomyoma of the heart, sometimes causing failure; (3) in the *eye*, nodular or cystic lesions; (4) in *bone*, osteoporosis, thickenings, osseous islands and cysts; (5) in the *brain*, cortical and subependymal nodules containing abnormal or neoplastic glia and neurons, which frequently calcify and are visible roentgenographically. The symptoms are seizures and usually mental deficiency. Treatment is limited to symptomatic relief of the seizures.

*Neurofibromatosis* or *von Recklinghausen's disease* is inherited as a nonsex-linked dominant. The lesions are sharply outlined *café-*

FIG. 318. Unusually extensive calcification in Sturge-Weber's disease.

*au-lait* areas on the skin, cutaneous and subcutaneous neurofibromas which are often pedunculated, neurofibromas along cranio-spinal nerves and roots, osteitis fibrosa cystica disseminata without hyperparathyroidism and multiple central nervous system lesions which are mostly nodules similar to those of tuberous sclerosis, or are located in the aqueduct or central canal. Localized gigantism may occur, and neurofibromas may undergo sarcomatous degeneration. Four related syndromes are (1) glioma of the optic chiasm with extensive *café-au-lait* marks; (2) pheochromocytoma, 10 per cent of which have associated *café-au-lait* patches or neurofibromas; (3) neurofibromatosis, cysts in the arachnoid, deepened middle cranial fossa, elevated sphenoidal wing and pulsating exophthalmos; (4) neurofibromatosis with generalized craniospinal nerve involvement and

muscular wasting resembling interstitial hypertrophic polyneuritis. Treatment is limited to removal of locally troublesome neurofibromas, particularly those on nerve roots, which compress the brain stem or cord.

*Encephalo-trigeminal angiomatosis* or *Sturge-Weber's syndrome* is genetically not completely understood. The distinctive feature is a large telangiectasis or port-wine stain, trigeminal in distribution, involving skin, scalp, skull and meninges. It is most common in the ophthalmic division, but may extend downward over the face. The typical, double-contoured opacities in the roentgenogram of the skull (Fig. 318) represent intracortical calcification and ferrugination secondary to circulatory slowing, and may appear within the first year of life. Congenital glaucoma and buphthalmos on the affected side are due to nevi in the choroid; there is crossed hemiparesis and hemianopsia, the vault on the affected side is small, and the skull is thick. Telangiectasis, especially on the upper extremity, may result in localized gigantism. The patients are often mentally defective and have lateralized seizures; sub-arachnoid hemorrhage occurs rarely. Local resection of the intracranial nevus or hemispherectomy may relieve seizures; glaucoma usually requires surgical treatment. Other treatment is symptomatic.

*Von Hippel-Lindau's disease* comprises hemangioma of the retina, hemangiomatous cysts of the cerebellum and spinal cord and cysts of the kidney, pancreas, liver and testes. It is hereditary, but its mode of inheritance is not clear. The retinal lesions cause retinal detachment and blindness; they require coagulation. Cerebellar cysts symptomatically resemble other cerebellar tumors and, though sometimes multiple, are usually operable.

## CONGENITAL VASCULAR LESIONS

These include saccular aneurysm, congenital arteriovenous fistulas, venous angiomas and telangiectases. Despite their congenital origin, clinical manifestations may appear at any time.

*Saccular aneurysms* in childhood arise from stumps of the arteries, which normally disappear in fetal life, or from thin spots at major arterial bifurcations; their incidence is high in coarctation of the aorta. Rarely

they are acquired, either as mycotic aneurysms or from other local arterial disease. Three fourths of cerebral aneurysms are located anteriorly on the circle of Willis, one fourth posteriorly or on the basilar system. The symptoms are (1) localized palsies due to pressure of the aneurysm (those of the third, the sixth and the ophthalmic division of the fifth cranial nerves being commonest) and (2) generalized manifestations due to rup-

ture, subarachnoid hemorrhage and local damage to the brain. Incomplete rupture is common. There are sudden, severe headache, vomiting, loss of consciousness and convulsions; the clinical findings include nuchal rigidity, fever, flame-shaped or subhyaloid retinal hemorrhages, altered consciousness and bloody cerebrospinal fluid under increased pressure. The initial mortality rate is about 40 per cent. Such leaks tend to recur and subsequent bleeding is more likely to dissect into the brain and produce hemiplegia. With each recurrence the mortality is about the same. Massive rupture is usually rapidly fatal.

*Congenital arteriovenous fistulas* are composed of one or several hypertrophied feeding arteries, a mass of communicating vessels often having aneurysmal dilatations, and a tangle of arterialized draining veins (Fig. 319). They may be anywhere in the brain or cord. Fistulas between the posterior cerebral arteries and the galenic system compress the aqueduct and may produce hydrocephalus; some form long tracts from the optic papilla to the midbrain. They usually become symptomatic in one of three ways: (1) migrainous headaches followed by lateralized seizures and, after several attacks, hemiparesis on the affected side; (2) evidences of subarachnoid hemorrhage or massive intracerebral bleeding which occurs without warning; and (3) increased intracranial pressure, due to enlargement of the malformation. Manifestations include a cranial systolic bruit, best heard over the eyeball and diminished by carotid compression, dilatation of scalp veins and often polycythemia.

*Venous angiomas* on the surface of the cortex or in the subependymal area do not produce a bruit and do not progress as do the arteriovenous fistulas. Their manifestations are usually focal seizures which appear early and are possibly due to thrombosis in the malformation. *Telangiectases* are most commonly found in the pons; thrombosis or rupture may occur.

The spinal cord may be involved by any of these malformations, though saccular aneurysm is rare. The manifestations are pain due to compression of the cord and subarachnoid hemorrhage. At times there is a cutaneous nevus over the cord defect.

**Diagnosis.** Spontaneous subarachnoid hem-

FIG. 319. Intracranial arteriovenous fistula and aneurysm. Note large feeding vessels.

orrhage or intracranial bleeding always suggests such a vascular lesion. Prior to rupture, aneurysm may be suspected from otherwise unexplained unilateral ocular palsies; arteriovenous fistulas, if a bruit is associated with lateralized signs and headache. Polycythemia with arteriovenous fistula may be intense, and, if the bruit is transmitted to the heart, congenital heart disease may be suspected. Brain tumor is the principal differential consideration and must usually be excluded by angiography.

**Treatment.** If a saccular aneurysm is demonstrated, it should be removed if it is in an operable site. Subarachnoid hemorrhage is treated with complete bed rest for four to six weeks, and sedation and lumbar puncture for relief of headache if it can be accomplished without a struggle. Hypothermia may be used at the onset. Some time in this period, usually in the second week, angiography should be done and operable lesions removed. Aneurysms on the left side or posteriorly placed are not usually favorable for operation; anterior, right-sided ones may be. Arteriovenous fistulas and venous angiomas are seldom operable; if they produce increased pressure, ligation of feeding arteries may be helpful for a time, but eventually these lesions fill from all the major arteries of the brain.

# EXPANDING LESIONS AND INCREASED INTRACRANIAL PRESSURE

The lesions to be discussed in this division, though of widely differing nature, all cause intracranial hypertension, and so are grouped together.

## INTRACRANIAL PRESSURE

**Physiologic and Anatomic Considerations.** The skull and vertebrae constitute a rigid case, vented to the outside only through the vascular system; they enclose the central nervous system and its membranes, a huge vascular bed, and cerebrospinal fluid under a pressure varying normally from 60 to 180 mm. of fluid, with an average of about 120 mm. The pressure of the cerebrospinal fluid is equated with the intracranial pressure. Volume change in any of the intracranial components is reflected in changed cerebrospinal fluid pressure, change in relative volumes of intracranial components, or both.

Cerebrospinal fluid is formed in the choroid plexuses of the four ventricles and in perivascular spaces of the brain and subarachnoid system by filtration and secretion. The process involves a two-way exchange at least of water and certain ions between blood and cerebrospinal fluid. The volume of this exchange is large, far exceeding the net formation of cerebrospinal fluid, which varies from 45 to 130 ml. of fluid per day in the ventricles alone. Water, most monovalent electrolytes and protein are added to cerebrospinal fluid in the ventricular and subarachnoid spaces; water is added more rapidly in the subarachnoid space, as protein probably is, but sodium and chloride excretion is mainly in the ventricles. The fluid is moved through the ventricles into the subarachnoid space and finally to the great absorptive bed of the arachnoidal villi of the dural sinuses, the spinal and some cranial nerve foramina.

Pressure and circulation of cerebrospinal fluid are the result of mechanical and vascular factors. Hydrostatic pressure alone accounts for about 50 mm. in the horizontal position; it falls in the head-up position and rises in the head-down position. The principal regulating factor is pressure in the cerebral vascular bed, the cerebrospinal fluid pressure rising or falling sharply with changes in arterial pressure, but accommodating smoothly

to slow changes. Sudden changes in venous pressures cause similar fluctuations. Additions to or removal of cerebrospinal fluid, though reflected in an immediate fall or rise, is rapidly compensated by a decrease or increase in cerebral venous volume.

Maintained increased intracranial pressure without a space-taking lesion represents a primary abnormality of one of the space-taking components within the skull, followed by secondary changes in the others. Formation of cerebrospinal fluid itself may be increased with meningitis, papilloma of the choroid plexus, benign increased intracranial pressure and "toxic hydrocephalus." Obstruction to the flow of cerebrospinal fluid causes a rise in pressure, but formation of fluid persists until pressures in excess of 700 mm. of fluid are attained. Increase in arterial pressure does not result in a persistent intracranial hypertension unless it is extreme or paroxysmal; the total blood flow remains constant. Venous drainage without the skull is so well provided with anastomoses that obstruction, unless close to the heart, causes little change in pressure; within the skull, sinus thrombosis, unless it is extensive or involves the posterior sagittal sinus or torcular or the usually larger right lateral sinus, may have no persisting effect at all.

Space-occupying lesions increase intracranial pressure by their own bulk and by compression on the ventricular system with production of obstructive hydrocephalus. They are compensated for initially by reduction in cerebrospinal fluid volume, but ultimately the vascular component suffers and the total intracranial blood flow is reduced. A significant increase of tissue fluid in edema of the brain causes similar effects.

**Clinical Features.** Headache, the most common complaint, is due more to distortion of pain-sensitive meninges and basal blood vessels than to pressure itself. Blunting of intellect, forgetfulness and, in the young child, fretfulness and irritability are common. Low-pitched, roaring or buzzing tinnitus, giddiness, vomiting, diplopia and sometimes visual loss due to extreme papilledema are additional manifestations.

The patient may be dull and given to rubbing the face or nose. Young children often

have separated sutures, a cracked-pot note on percussion and a nonlateralized bruit over the head. Focal neurologic signs, except for the nonlocalizing abducens palsy, are absent. Papilledema is almost the rule, unless extreme myopia or previous optic atrophy prevents it. The retinal veins become distended and pulsation diminishes; the disk reddens and its polar and nasal margins blur, and the cup disappears. Extreme elevations, hemorrhages, arterial narrowing, exudates, retinal folds and pallor are late severe signs which may develop rapidly on pre-existent swelling. Visual acuity and the visual fields, except for enlarged blind spots and later concentric constrictions, are well preserved; these distinguish papilledema from optic neuritis. Alterations in consciousness, projectile vomiting, bradycardia and bradypnea, systemic hypertension and seizures are late events brought about by brain stem distortion, ischemia and disturbed cortical circulation.

**Hernia Cerebri.** The intracranial cavity is incompletely divided into compartments by dural and osseous septa. The posterior fossa communicates with the anterior and middle fossae through the tentorial incisure; inferiorly, it communicates with the spinal thecal space through the foramen magnum. Shifts of supratentorial contents can occur toward either side across the midline, but, if sufficiently great, always cause herniation of brain into and through the tentorial notch. Shifts of infratentorial contents may herniate the cerebellar tonsils downward through the foramen magnum or the anterior lobe of the cerebellum upward through the notch. These shifts with resultant herniations of brain substance and pressure on neural and vascular structures are the basis for the signs and symptoms of severe increased intracranial pressure.

Increase of the supratentorial volume from whatever cause forces brain substance into the tentorial notch. Anteriorly the uncinate lobe and posteriorly the hippocampal gyrus are pushed downward to form a ring about the mesencephalon. The aqueduct and cerebrospinal fluid cisterns traversing the notch are compressed and obstruct the flow of fluid; the posterior cerebral arteries and the galenic veins are squeezed, causing hypoxia in the posterior thalamus and occipital lobes and venous congestion of the interior of the hemispheres. The sixth and third nerves are stretched and pinched, producing abducens, oculomotor or pupillary palsy (Fig. 320). Finally, the brain stem is itself deformed,

and hemorrhages occur into it. Acute anterior hernia of the uncinate lobe compresses the hypothalamus, damaging it by direct and vascular compression. Such brain stem hemorrhage and hypothalamic damage must in most cases be irreversible; small hernias need not be. It has been suggested that uncinate herniation during birth produces temporal lobe scarring which may later become epileptogenic.

Increase in the bulk of the posterior fossa contents forces cerebellar tonsils into the foramen magnum, causing meningeal irritation, nuchal rigidity and ultimately fatal medullary compression, or the anterior lobe may be forced upward through the tentorial notch, compressing the brain stem from above.

The development of shifts and hernias is affected by the rate of increase of intracranial pressure. Slowly increasing masses may, through reducing cerebrospinal fluid and vascular volume and producing local brain atrophy, cause little or no distortion or increased pressure. Slowly developing hernias may be well tolerated; at any time a sudden change in pressure, such as may follow a small hemorrhage into a pre-existing hematoma, the overhydration of an infant, an ill-advised lumbar puncture or even the increase in blood volume on coughing or straining, may convert a well tolerated hernia into a symptomatic or even a lethal one.

The cranial sutures of the infant and

FIG. 320. Tentorial herniation with acute subdural hematoma. A, Margin of herniated hippocampal gyrus; B, compressed oculomotor nerve; C, hemorrhages into brain stem.

young child are separable and provide some control of otherwise increasing pressure. This separation may occur suddenly, explaining sudden remissions in the history of expanding intracranial lesions of young children.

**Treatment.** Mildly or moderately increased pressure is an indication for immediate study, but not for immediate treatment. The best indicator of borderline cases is papilledema. If it is high grade with hemorrhages, arterial narrowing, pallor of disks, visual loss or recurrent transitory blurring or blacking out of vision, immediate intervention is necessary. Signs of herniation also indicate prompt treatment.

The procedures are all decompressions; most are surgical, and their choice depends on the specific lesion and the preference of the surgeon.

**Chemical decompression.** Hypertonic solutions, 50 per cent glucose or sucrose, 10 per cent sodium chloride solution or salt-poor serum albumin injected intravenously will cause immediate shrinkage of the brain through the osmotic effect on tissue fluid. The improvement is transitory and the procedure valuable *only for controlling herniation and reducing brain bulk at operation*; these should not be used to maintain patients with mass lesions, and they have no effect on edema of toxic or inflammatory origin. A 25 per cent solution of urea has a more maintained effect, and its use over prolonged times, renal function being adequate, may be valuable. Acetazolamide, though it may decrease cerebrospinal fluid formation and pressure, is not constant in its effect; administered parenterally, it may increase the pressure.

**Removal of cerebrospinal fluid.** When intracranial pressure is high, the volume of cerebrospinal fluid adequate and the danger of herniation slight, repeated lumbar punctures reduce discomfort and may prevent progression of papilledema. The procedure is dangerous with mass lesions and often so with severe cerebral edema. Its greatest value is in "benign increased intracranial pressure."

When danger of herniation exists, ventricular puncture or closed constant ventricular drainage may be used as semi-emergency procedures. These procedures require an adequate cerebrospinal fluid volume and hence are inapplicable for the small ventricles of a swollen brain. Tapping of ventricles under high pressure may produce disastrous hemorrhage from the subependymal veins or fatal upward herniation of the cerebellum in the presence of a posterior fossa lesion.

**Surgical decompression.** The ideal treatment is internal decompression by removal of the lesion. With inoperable lesions producing obstructive hydrocephalus, a suitable bypassing procedure, such as a variant of the Torkildsen tube, or ventriculostomy is indicated. Generalized swelling or increased pressure, otherwise uncontrollable, requires extensive decompression by large fronto-temporo-parietal flaps. When severe herniation has occurred at the tentorial notch or foramen magnum, immediate decompression of the medulla or section of the free margins of the tentorium may be lifesaving.

## BRAIN TUMOR

**Epidemiology.** Neoplasms of the central nervous system make up a large portion of tumors in childhood. There is no general predilection for race or sex. There is a definite age incidence; tumors are rare in infancy, but increase rapidly to a peak at the five- to six-year age level, probably owing to the high incidence of medulloblastoma at this age; thereafter a more uniform level is maintained through childhood.

**Pathology.** Two factors, histologic structure and location, require particular consideration. About 75 per cent of intracranial tumors in childhood are gliomas, of which two thirds are astrocytomas and medulloblastomas. Ependymomas, brain stem gliomas and gliomas of the hemispheres constitute another 15 per cent, and the remainder are craniopharyngiomas, meningiomas, sarcomas, pituitary adenomas, hamartomas, hemangiomas and dermoids. The acoustic neurinoma, meningioma and pituitary adenoma of adult life are rare, as are metastases from noncerebral neoplasms.

Sixty to 70 per cent of brain tumors in childhood are beneath the tentorium cerebri, in contrast to a reverse pattern in the adult. Of the supratentorial tumors, more than half are in the midline. Thus the gravity of the problem in children is pointed up by the facts that about three fourths of all brain tumors are incapable of being completely removed, owing to their cellular pattern; that about half of them are also difficult or impossible to remove, as a result of their location, and that others are so situated in relation to the brain stem or to the ventricular system that functional embarrassment of these structures is a possibility.

**Clinical Manifestations.** The general symptomatology of brain tumor in childhood is

that of increased intracranial pressure. *Vomiting* is seldom absent. It usually occurs in the morning around breakfast time, often without nausea, the child returning at once to his meal; rarely it is pernicious. Only late in the course does classic, projectile vomiting appear. *Headache* is less constant and is encountered in only about 70 per cent of cases, perhaps in part because the child's descriptive powers are limited. Like vomiting, it is more frequent when the child rises from sleep. It is usually bifrontal or suboccipital; suboccipital headache may herald tonsillar herniation and be accompanied or followed by stiff neck. Persistently lateralized headache, especially if accompanied by percussion tenderness, is more suggestive of abscess than tumor. *Diplopia* is usually due to abducens palsy, the sixth nerve or nerves being stretched by intracranial deformity; such palsy has no localizing value. It is responsible for most of the complaints of visual failure, since papilledema itself usually produces little disturbance in acuity. *Enlargement of the head* is most frequent in children under four years. *Mental change* is usually a matter of lethargy, indifference or some irritability, giving way to drowsiness, stupor, coma and death. *Convulsions* are rare, generally indicating tumor of a cerebral hemisphere. In late stages of cerebellar tumor, "cerebellar fits" with head retraction, rigidity and extension of limbs and disturbances of pulse and respiration indicate intermittent decerebration, probably by vascular disturbance of the mesencephalon; these signs are of ominous portent.

**Regional characteristics.** The common *infratentorial tumors* are cerebellar medulloblastoma, cerebellar astrocytoma, brain stem glioma and ependymoma.

The *medulloblastoma*, most common of all brain tumors of childhood, has its peak incidence around five years of age and occurs twice as often in boys as in girls. The tumor usually originates in the posterior vermis; of all tumors, it most frequently spreads to the meninges of the brain and cord. The course is rapid, early morning vomiting and unsteadiness of gait being soon followed by enlargement of the head. Most children have papilledema and sutural separation; the gait disturbance is one of disequilibrium. Except for hypotonia, cerebellar signs are slight in the limbs. Fifth or seventh cranial nerve palsies and pyramidal signs are evidence of compression or invasion of the brain stem; nystagmus is common. Obstructive hydrocephalus

is constant. Nuchal rigidity, cerebellar seizures and even cord signs are late events. Total removal is impossible; the best treatment is decompression and roentgen therapy. Survival is usually less than one year.

The *cerebellar astrocytoma* has a peak incidence around eight years of age and a slight predilection for the female. The tumor usually begins close to the midline and is often cystic with a tough, gliosed wall enclosing a mural nodule and containing a yellow, protein-rich fluid. Occasionally the mass invades the cerebellar peduncles or brain stem. The course is slower, and lateralizing cerebellar signs, hypotonia, ataxia, diminished reflexes, rebound phenomenon and nystagmus are usually demonstrable. Headache and vomiting are later and less persistent manifestations than with medulloblastoma; papilledema is too often allowed to proceed to irreversible optic atrophy. Total surgical removal is usually possible, and a complete cure is attainable. Roentgen therapy is not very effective and should be used only for tumors which have infiltrated too extensively to permit removal.

*Brain stem gliomas* account for 8 to 10 per cent of brain tumors in children; there is no sex preference; the peak incidence is about the seventh year of age, but no age except perhaps infancy is exempt. The common syndrome is one of multiple cranial nerve palsies, particularly of the seventh, sixth, ninth and tenth nerves and of the sensory portion of the fifth nerve combined with ataxia of the trunk, mild pyramidal signs usually without spasticity, little sensory loss and vomiting without other evidence of increased pressure. Cerebrospinal fluid pressure is elevated only late, and the fluid, which is usually normal, infrequently contains 5 to 20 lymphocytes and a slight excess of protein. Pneumoencephalography demonstrates backward and upward shift of the floor of the fourth ventricle 3.5 to 3.8 cm. beyond the clivus, encroachment on pontine cisterns and some ventricular dilatation. Hypersomnia and hyperthermia are evidence of extension into the upper brain stem and hypothalamic area. The tumor usually begins in the deep strata of the pons. Such tumors are inoperable, but the course is sometimes slow, and roentgen therapy may permit a surprisingly long survival in fair condition.

*Ependymoma* in childhood has no sex or age predilection. The initial symptom is almost always vomiting followed by headache, unsteady gait, enlarging head and pyramidal and cerebellar signs. The clinical pattern is

FIG. 321. Craniopharyngioma in a boy of 8 years. Note fluffy suprasellar calcification, enlarged sella turcica, digital marking of skull, and early sutural separation.

variable, since the tumor invades and exerts pressures in widely differing directions. Regression of symptoms is also often a feature. Flecklike calcifications evident on the roentgenogram and internal hydrocephalus are common. The tumor is best treated by incomplete internal compression and roentgen therapy.

The common *supratentorial tumors* are those of the suprasellar and chiasmatic regions, of the thalamus and posterior third ventricle and of the hemispheres.

*Tumors of the suprasellar and chiasmatic regions* include craniopharyngioma and glioma of the optic chiasm. The *craniopharyngioma*, or suprasellar cyst, occurs in late childhood and through adult life. It is a solid tumor, at times with a cyst above it. The symptoms are those of increasing pressure due to distortion of the foramina of Monro and third ventricle, of compression of the optic chiasm, causing bitemporal field defects and later optic atrophy, and of pressure on the pituitary and hypothalamus, leading to arrest of growth and osseous development, fatigability, diabetes insipidus and disturbances of the sleep rhythm. Any one of these manifestations may bring the child to the physician, but since the visual and the hypophysis-hypothalamic changes advance slowly, headache and vomiting are the usual chief complaints. Hypothalamic attacks of semistupor, fever, cardiac irregularities and miosis may occur. The child usually appears less than his stated age, his head somewhat large.

The roentgenogram of the skull reveals separated sutures, very often suprasellar calcification and some sellar deformity (Fig. 321). Hypoglycemia, a flat glucose tolerance curve, diabetes insipidus, a high eosinophil count, lowered excretion of 17-ketosteroids and hypotension are common. The optic disks may be elevated, atrophic or normal. Surgical removal of the tumor in toto is almost impossible. The usual procedure is drainage of the cyst and removal of the cyst wall and as much of the solid tumor as is accessible. Preoperative and postoperative corticosteroids greatly reduce operative mortality; postoperative diabetes insipidus is frequent. Roentgen therapy will often control the solid portion of the tumor for years.

*Glioma of the optic chiasm* initially causes visual disturbances; later there are manifestations of increased pressure and of hypothalamic involvement. It is often accompanied by extensive cutaneous *café-au-lait* spots. Optic atrophy is more frequent than papilledema. Excavation beneath the anterior clinoids is a common roentgen finding. The tumor is inoperable; roentgen therapy is indicated.

*Tumors of the posterior third ventricle* are pinealomas, gliomas and hamartomas. All produce obstruction early in the course with signs of increased pressure. The pineal neoplasms compress the mesencephalon from above and cause pupillary dilatation and failure of upward conjugate gaze, the syndrome of Parinaud. They may produce precocious puberty in the male by pressure in the hypothalamic area. Gliomas in the thalamus or hypothalamus may cause similar hypothalamic disturbance, together with increased pressure and frequently hemiplegia. They are best treated by draining the ventricle with by-passing tubes and by radiation.

*Tumors of the hemispheres* are gliomas, ependymomas of the ventricle and sometimes sarcomas. Clinical manifestations are hemiplegia, seizures and those of increasing pressure. They are frequently enormous in size. Treatment, surgically or by radiation, is unsatisfactory in almost all cases.

**Treatment.** In general, treatment is unsatisfactory. Complete cure, for practical purposes, is restricted to the cystic cerebellar astrocytoma, and thus to only about 15 per cent of children with intracranial neoplasms. Death is hastened by intervention in about an equal percentage of instances. Even when complete cure is impossible, relief of symptoms and return to enjoyable life for months

or years is often possible, and should never be denied a child. An attitude of pessimism and nihilism breeds inadequate study of a case and leads in turn to death or permanent disability from treatable lesions. When there is a reasonable likelihood of an expanding lesion, diagnostic study should not cease until the lesion is located, its nature determined beyond reasonable doubt and the appropriate therapy decided.

Definitive study of such cases is a matter for experienced neurosurgeons and neurologists; the responsibilities are great, and the diagnostic procedures themselves are often major operations. The pediatrician performs two roles: the vital one of suspecting the lesion and initiating study, and support and maintenance of a critically ill child. Careful correction of water and electrolyte disturbances, corticosteroid or corticotropin therapy during operations about the hypothalamus, restoration of nutrition and maintenance of the patient's and parents' morale are responsibilities he must share.

## EXTRACEREBRAL ACCUMULATIONS OF FLUID

Subdural hematoma is an accumulation of blood, its degradation products and fluid within the subdural space. It may be acute, subacute or chronic and usually results from direct trauma to the head.

### CHRONIC SUBDURAL HEMATOMA OF INFANCY

**Etiology.** Direct or transmitted trauma to the head at any age may produce bleeding into the subdural space. In the older child or in the adult a positive history of trauma is elicitable in 80 per cent of cases; in infants relationship to trauma is less clear. Molding and other trauma of the head at birth are considered possible causes, but supportive evidence is inconclusive. The lesion is not common in premature infants, in whom the possibility of molding trauma to the head is very great. Scurvy and purpuric states increase the hazard; in hemophilia subdural hematoma is rare. Deliberate violence is probably more often the cause than is suspected.

**Epidemiology.** More common in male than in female infants, subdural hematoma is rare in the newborn and rarely demonstrated in the stillborn. The incidence rises sharply in the second month of life to a peak by about four months, followed by a rather sharp fall and virtual disappearance by fourteen to six-

teen months of age. Ill-cared for, unwanted infants, being more subject to trauma, are more frequently affected, and the illness is rarer on private than on ward services.

**Pathology.** The subdural space is occupied by a sac which usually extends frontally and laterally over the hemispheres; it is bilateral in about 80 per cent of cases. The dural wall of the sac is thicker, heavily vascularized and fused with the dura mater; the arachnoid wall is thinner, less vascularized and less firmly attached to the meninx. This sac contains a variable mixture of fresh and old blood and xanthochromic fluid; the protein content is high, and there are many white cells. The brain beneath is compressed and its leptomeninx often thickened. In long-standing cases the cortex shows considerable convolutional atrophy.

**Pathogenesis.** At the time of trauma delicate bridging subdural veins, most numerous along the falx (Fig. 322), are torn. Small hemorrhages occur in the subdural space. Originally insignificant in amount, this blood breaks down, and imbibition of fluid occurs across the arachnoid membrane. The break-

FIG. 322. Relation of subdural veins to dura mater, dural sinuses, arachnoidal granulations and arachnoid membrane. Tearing of these veins may cause subdural hematoma. (Preparations of D. H. Padgett.)

FIG. 323. Calcified subdural membrane in a microcephalic idiot. Right subdural hematoma drained in infancy (note trephine), left side not explored. Calcified membrane discovered years later.

down products of blood stimulate the growth of connective tissue and capillaries, largely from the dura. As fluid increases the width of the subdural space, these capillaries are torn, further hemorrhage occurs, and the lesion enlarges. If unrelieved, the mass expands the skull, ultimately causing cerebral atrophy or death from compression and herniation. At any point the lesion may spontaneously arrest, only to be discovered as a calcified membrane over the brain in older defective patients. Additional trauma may increase symptoms due to an already existing sac. The formation of such sacs occurs more readily over a previously atrophic brain, the *hematoma ex vacuo*.

**Clinical Manifestations.** The most characteristic ones are a restless irritability and failure to thrive. There is a history of convulsions and vomiting in half the cases and of recurrent fever, drowsiness and birth or post-natal trauma in descending order. On admission, more than half the infants have fever; the reflexes are hyperactive, but frank paralysis and hemiplegia are uncommon. About half of the infants have bulging or tense fontanels, and the head is measurably enlarged, with a square, boxlike expansion of the vault in about one third. The scalp is tight and glossy, and the scalp veins are dilated. Almost 90 per cent of the infants ultimately show retinal hemorrhages, frequently subhyaloid; this may be a late change and is often absent at the

time the diagnosis is made. Strabismus, pupillary inequality and ocular palsies are infrequent and of little localizing value.

**Laboratory Data.** One third to one half of the infants have an anemia of blood loss and a low serum protein level, each of which is progressive if untreated. Sutural separation is demonstrable roentgenographically, but fractures are rare. Multiple fractures of long bones suggest trauma as a cause of the subdural bleeding. The electroencephalogram may reveal reduction in voltage over very large hematomas; minor asymmetries, spikes or slowings are evidence only of brain injury. The cerebrospinal fluid is often under increased pressure and often contains red blood cells, a slight excess of white cells and increased protein. The definitive diagnostic procedure is a carefully performed subdural puncture (see p. 1071); fluid of any sort in excess of a milliliter or two is an abnormal finding.

**Differential Diagnosis.** Subdural hematoma must be distinguished from hydrocephalus, chronic meningitis and brain tumor, and from other fluid accumulations without the brain, notably a subdural effusion complicating meningitis.

**Treatment.** The basis of treatment for subdural hematoma at any age is removal of the abnormal fluid with as much of its surrounding membrane as possible. An immediate surgical approach results in a high fatality rate and should not be considered. Reasonably good end results can be expected from a regimen combining subdural drainage with craniotomy at a later date, if this proves necessary.

No more than a total of 30 ml. of fluid should be removed from the two sides in the initial or subsequent daily aspirations. The hemoglobin and serum protein levels should be restored by transfusion, and any infection should be treated. The infant's condition usually improves rapidly. Frequently the hematomas reduce in size and may disappear from tapping alone. If after eight to ten days of aspiration no real reduction of fluid has occurred, burr holes are placed over the vertex, and the sacs are washed clean by catheter. The fluid then often ceases to accumulate. If this occurs, it is the practice in some clinics to stop at this point. In others small flap craniotomies are performed, and as much of the adherent membrane and contained clot as possible is removed. Even after craniotomy, fluid may continue to accumulate for a time, and aspiration may still be neces-

sary, since all the membrane can seldom be removed. With this regimen mortality may be kept well below 5 per cent with complete recovery and without mental limitation in better than 50 per cent of the cases. The best prognostic sign is the condition of the brain at the time of operation; if severe atrophy exists, the prognosis is poor.

### SUBDURAL EFFUSION

In the course of pyogenic meningitis, accumulations of protein-rich, xanthochromic, sometimes encapsulated fluid occur in the subdural space. These are thought to be due to an effusion of fluid across an inflamed arachnoid or from thrombosed subdural veins into the subdural space, where the exudate stimulates encapsulation and grows by imbibition and capillary rupture, similar to a subdural hematoma. Curiously, this striking lesion was not noted in the preantibiotic era; its exact pathogenesis is still uncertain.

The lesion can occur at any age and with any of the pyogenic meningitides. *Hemophilus influenzae* is responsible for more than 50 per cent of the cases, and mainly in infants of three to eight months of age. Effusions should be suspected in chronic pyogenic meningitis, or in any treated meningitis when the fever fails to abate after three or four days of adequate therapy, when convulsions or neurologic signs appear, when cerebrospinal cultures remain positive or when the infant vomits or fails to thrive. The treatment is that of subdural hematoma, except that effusions less often have well developed membranes and more often respond to daily tapping.

### ACUTE SUBDURAL HEMATOMA, SUBDURAL HYGROMA AND CHRONIC SUBDURAL HEMATOMA IN OLDER CHILDREN

*Subdural bleeding* can be expected in most instances of severe head injury; if the condition of such a patient is worsening steadily, with deepening stupor and advancing hemiparesis, exploration and aspiration through burr holes are indicated as an emergency measure.

*Subdural hygroma*, in the strictest sense, is an accumulation of cerebrospinal fluid in the subdural space, to which it gets ingress through a valvelike rent in the arachnoid. It is always traumatic, and not clinically separable from epidural or subdural hematoma. It is rare, and many fluid accumulations so diagnosed are really effusions or leptomenin-

geal cysts containing fluid with an unusually low protein content.

*Chronic subdural hematoma in older children* is rare; the clinical syndrome is that of headache, mild hemiparesis and papilledema. At times there are vomiting and/or seizures. Visual field defects are rare; abducens palsy may appear. Angiography is often diagnostic, but the definitive procedure is exploration through a burr hole followed by appropriate craniotomy.

### EPIDURAL HEMATOMA

This is an accumulation of blood between dura and bone. The cause is trauma; the lesion accounts for about 2 per cent of pediatric hospital admissions for head trauma. One half of the cases occur before two years of age. In the older child or adult the classic course is that of head trauma with brief loss of consciousness followed in turn by a lucid interval and then by deepening stupor, homolateral pupillary dilatation, contralateral hemiparesis, slowing pulse and respiration, rising blood pressure and death within the ensuing hours. The bleeding is arterial, usually as a result of a linear fracture which lacerates the middle meningeal vessels. In the child under two years of age, loss of consciousness is less frequent, the fracture usually diastatic rather than linear, and the bleeding venous as well as arterial. The course is often slower, and the hematoma may become large enough to produce extensive blood loss, and the symptoms are those of shock rather than increasing pressure and brain stem compression.

The common signs at any age are lacerations of the scalp, drowsiness, stupor and/or coma. Pupillary dilatation or advancing oculomotor palsy is almost always homolateral, rarely contralateral; hemiparesis is almost always contralateral, rarely homolateral. The temperature is often subnormal and the pulse pressure wide. In the early stages the pupillary and hemiparetic signs, as well as the slowing pulse and respiration, may be inconspicuous if the child is kept roused by examinations. Careful, quiet observation in a private room, with regular frequent recordings of pulse and respiration, is better than repeated vigorous examination.

This condition is a surgical emergency, and when its existence is considered likely, operation should not be delayed. Roentgenographic examination is valuable if the child's condition permits; other studies and especially

lumbar puncture are best avoided. Since brisk hemorrhage is often encountered, a blood transfusion should be started before or be immediately available during operation. Survival and functional recovery depend on early, successful evacuation of the clot and arrest of bleeding.

## BRAIN ABSCESS

Focal sepsis in the brain in childhood generally occurs (1) by extension from infection in the mastoid, paranasal sinuses, scalp or skull; (2) metastatically from bronchopulmonary, pleural, cardiac or other remote sources; (3) as a complication of congenital cyanotic heart disease or pulmonary arteriovenous fistulas; or (4) rarely from penetrating wounds. In a small percentage of instances no source is found. Almost any pathogen can be responsible.

Infection from sources about the head is by direct extension or along thrombosed vessels and usually involves immediately adjacent cerebral tissue. Hematogenous spread localizes at the junction of the cortex and white matter, with slight preference for the left hemisphere. A focus of septic encephalitis is established which may enlarge rapidly and produce paralysis, coma and death. More often the lesion becomes walled off, and an abscess forms. As it expands, there is edema of the surrounding area. Extension is toward the ventricle, and secondary abscesses in the wall are common. Rupture usually occurs into the ventricle; some abscesses become sterile; the wall calcifies, and the lesion becomes static.

There are three stages. The first is characterized by focal encephalitis. The patient, already ill with a primary infection, has an elevation of temperature, is drowsy and complains of headache. He may have a convulsion, or there may be meningeal signs. Improvement occurs in a day or two, especially with antibiotic therapy. The second stage, during which the abscess is enlarging, is a relatively quiet one. For days or weeks the child is only vaguely ill, listless, occasionally feverish to 100° or 101° F., and complains of some headache, usually frontal. Neurologic signs are slight, unnoticed or absent. Eventually the tempo of illness increases, headache is worse and more localized and a seizure often occurs. Focal signs appear, the optic disks blur and the cranial sutures may separate. At any moment the child may pass into the third stage, of decompensated increased

intracranial pressure with neurologic and cardiorespiratory signs of brain stem compression, or the abscess may rupture and be evidenced by high fever, meningeal signs, seizures and a decerebrate state.

Clinical signs depend on increased pressure and on the locus of the abscess. Drowsiness, headache, vomiting, sixth nerve palsies and papilledema are early manifestations. Since most abscesses are solitary and most are supratentorial, the common localizing signs are hemiparesis, visual field defects and aphasia. The frontal abscess is notably silent; lethargy and dullness are often the only signs. A cerebellar abscess produces lateralized hypotonia, ataxia, adiadochokinesis, coarse nystagmus mainly toward the side of the abscess and skew deviations. Percussion tenderness over the abscess is one of the most valuable of all localizing signs.

Leukocytosis, present during the first stage, is absent during the second one and becomes marked only with rupture of the abscess. Anemia of infection is usually present. Roentgenograms of the skull show only sutural separation or sellar demineralization; films of the chest, long bones, sinuses or mastoids may reveal an unsuspected infective focus. The cerebrospinal fluid in the first stage is marked by pleocytosis and elevated pressure, but the fluid is sterile; in the second stage, pressure and protein content are constantly elevated, and there may be a few cells. In the third stage, pressure, protein and cells increase; high pleocytosis indicates leakage or rupture, in which case pathogens may be cultured from the fluid. The electroencephalogram is a valuable tool, since the large zone of edema often produces lateralized and sometimes sharply localized delta waves; serial electroencephalograms are of diagnostic value in the differential diagnosis.

Four to 8 per cent of all patients with cyanotic heart disease or pulmonary arteriovenous fistulas suffer brain abscess. The etiology of these abscesses is not clear. They do not arise from bacterial endocarditis and a specific focus is rarely demonstrated. Relief of cyanosis by anastomotic procedures does not protect against cerebral abscess, which occurs in any form of cyanotic congenital heart disease. Clinically, diagnosis is difficult because a definite first stage is absent, and the symptoms of headache, irritability, recurrent fever and even sudden onset of localizing signs or hemiplegia are common in cyanotic heart disease. Only constant vigilance will detect the abscesses. Since these

children tolerate prolonged anesthesia poorly, repeated aspiration is the best means of treatment.

**Treatment.** Adequate antibiotic therapy probably often heals incipient abscesses during the first stage. An established abscess must be treated surgically. Two methods are used: In one the abscess is tapped through a burr hole, aspirated and thorium dioxide instilled to outline the cavity. Repeated aspirations are performed under roentgen guidance, and antibiotic therapy is continued until the abscess disappears. In the other the initial treatment is the same, but after some days the abscess is resected in toto. The purpose is to ensure cure and to minimize the incidence of seizures; the evidence for the latter is questionable. The writer favors the first method because it is simpler and less likely to leave neurologic residuals.

Case fatality rates average about 25 per cent, a rate that is far too high. Survivors have seizures in about 45 per cent of instances and hence should be maintained on anti-convulsant therapy for at least five years.

## INCREASED INTRACRANIAL PRESSURE

### WITHOUT MASS LESIONS

#### *DURAL SINUS THROMBOSIS*

Occlusion of dural sinuses results from neighboring or remote infection, sometimes from polycythemia or hemoconcentration, anemia, blood dyscrasias, slowing of circulation, trauma or tumor invasion.

The signs and symptoms are (1) those of the primary condition, such as chills, fever, leukocytosis, otitis media and marasmic state; (2) neurologic ones stemming from the region of the brain affected by venous stasis, edema or infarction; and (3) manifestations of increased intracranial pressure. Any or all may be present, and, conversely, all may be absent and the occluded sinus discovered incidentally.

**Superior Sagittal Sinus.** The occlusion is most often nonseptic and occurs as a rule in dehydrated, marasmic or toxic infants. The onset is abrupt; convulsions and single, or sometimes double, hemiplegia indicate extension of the thrombus into the superficial cortical veins. Stupor, head retraction, bulging fontanel, dilated scalp veins, papilledema and enlargement of the head are signs of obstruction of the sinus and of increased pressure. The cerebrospinal fluid often contains some red and white blood cells. The ventricles are

initially compressed by congestion and edema, but later enlarge, and the cortex atrophies. Incomplete occlusion with lateralizing neurologic signs and less marked increase of intracranial pressure is more common than complete occlusion and is less serious. This condition must be distinguished from the stupor, convulsions and rigidity of severe hypernatremia.

**Sinus Rectus and Galenic Vein.** Occlusion here is either septic or nonseptic. Sudden onset of coma, generalized convulsions and high intracranial pressure are accompanied by initial flaccidity rapidly changing to decerebrate rigidity. The cerebrospinal fluid is grossly bloody, and the child soon dies.

**Cavernous Sinus.** Thrombosis of this sinus is almost always septic, being secondary to infections about the orbit, face, pharynx, sphenoidal sinus or the petrous apex. The chills, fever, headache and leukocytosis of the severe infection are accompanied by drowsiness, but rarely by seizures or stupor. Edema and chemosis of the eyelids, protrusion of the eyeball, thrombosis of retinal veins and later low grade papilledema are associated with a decrease in vision and with extraocular palsies. Extension across the circular sinus to involve the other eye, meningeal signs and pleocytosis of the cerebrospinal fluid may occur; there is usually increased intracranial pressure.

**Lateral Sinus Thrombosis.** Evidence of otitis media, acute or chronic, is almost always present. The onset may be abrupt with septic fever, chills, leukocytosis and a positive blood culture, or it may be insidious with only signs of increasing intracranial pressure. If the onset is abrupt, contralateral facial weakness, sometimes contralateral seizures and rarely hemiparesis indicate spread of the thrombosis upward through the cortical veins across the hemisphere. Paralysis of the ninth, tenth and eleventh cranial nerves is due to thrombosis of the jugular vein, which may become palpable in the neck. There is headache, drowsiness and papilledema in about half of the cases. Differentiation from brain abscess may require ventriculography.

**Treatment of Dural Sinus Thrombosis.** Any infection must be appropriately and vigorously treated with antibiotics and surgical drainage when indicated. Anticoagulants to limit spread of the thrombosis are of doubtful value. Increased pressure, once the diagnosis is established, is best managed by repeated lumbar punctures, but if vision is threatened, subtemporal decompression may

be used. Surgical removal of the thrombus is seldom done since the clots recanalize rapidly.

### BENIGN INCREASED INTRACRANIAL PRESSURE

(TOXIC HYDROCEPHALUS, PSEUDOTUMOR CEREBRI, QUINCKE'S OR SEROUS MENINGITIS)

This term is used to identify a syndrome resulting from increased intracranial pressure and manifested by headache, papilledema, sixth nerve palsies, sometimes vomiting and absence of other neurologic signs. Though most common in young adult women, it occurs in childhood. Some cases have been identified as "silent" lateral or longitudinal sinus thrombosis, but others seem to follow various infections or slight head injuries, and the actual etiology remains obscure. The definitive diagnostic procedure is ventriculography, which reveals small, symmetrical, unshifted ventricles (Fig. 324). Treatment is by repeated lumbar puncture, with surgical decompression if vision is threatened; attempts at chemical decompression, as with acetazolamide have not been impressive. Elevated intracranial pressure may persist for months.

### HYDROCEPHALUS

Hydrocephalus is an abnormal increase in

cerebrospinal fluid within the intracranial cavity. It is not synonymous with an enlarged head, since the latter may be due to subdural hematoma or macrocephaly, whereas hydrocephalus may or may not notably enlarge the head.

A lesion which obstructs the flow of cerebrospinal fluid anywhere from point of secretion to point of absorption is the cause in almost all cases. Overproduction of cerebrospinal fluid by a tumor of the choroid plexus is a rare cause; dural sinus thrombosis seldom causes maintained hydrocephalus. The lesions vary widely; about one third are congenital defects, such as atresia or forking of the aqueduct, the Arnold-Chiari malformation, atresia of the foramina of Luschka and Magendie, occipital encephalocele, agenesis of the corpus callosum and failure of development of subarachnoid cisterns. Inflammatory lesions, either meningitis or reaction to bleeding from birth trauma, cause aqueductal gliosis and obliteration of subarachnoid systems. Rarely, meningeal deposits, lipid-laden phagocytes in gargoyism or multiple metastases are responsible. Tumors, abscess and angiomatous malformations are other causes.

Much of the pathogenesis is simple mechanics. The fluid system dilates above the point of obstruction; e.g., obstruction at Monro's foramen dilates one or both lateral ventricles, aqueductal lesions, the third and lateral ventricles; and obstruction at the fourth ventricular foramen or in the subarachnoid space enlarges all four. The obstruction may be partial, intermittent or complete; the symptoms may be rapid or slow and steadily advancing or remittent. Atrophy of the choroid plexuses is a late event, and fluid continues to be formed in their absence. Fenestrations may develop in the septum pellucidum, the membranous walls of ventricles or other points, and spontaneous bypassing of obstructed points occurs.

Though hydrocephalus is sometimes recognized before birth, most cases become manifest in the first few weeks or months of life. The fontanels widen and are moderately tense, and the skull enlarges in all diameters. The brow bulges; the sclera becomes visible above the iris, owing rather to upper lid retraction than to pressure on the orbit; the scalp becomes shiny, and scalp veins dilate. Failure of upward gaze, strabismus, hyperactive reflexes, mild diplegia and optic atrophy are additional manifestations; papilledema in the infant is rare. Irritability, failure to thrive

FIG. 324. Benign increased intracranial pressure or "pseudotumor" in a boy of 4 years. Sutures are separated, but ventricles are small and unshifted.

and a high-pitched cry are common. When the onset is later, or the progress less rapid, the head may enlarge much more in one plane than another, producing brachycephaly or scaphocephaly. The disproportion of the skull may help to locate the obstruction, a shallow posterior fossa suggesting aqueductal or third ventricular lesions.

If the brain is not seriously malformed, mental function remains surprisingly good; children with paper-thin cortex often have intelligence quotients within the normal range. Motor function is generally retarded, both by the weight of the head and by the actual neurologic impairment present.

The steps in management of hydrocephalus are as follows: (1) The existence of hydrocephalus must be established and its advancement proved by serial head measurement. (2) Surgically remedial lesions, particularly subdural hematoma, must be excluded. (3) The point of obstruction must be located and the child evaluated for a bypassing operation. Contraindications to operation are as follows: age under six months; cerebral cortex less than 1 cm. as shown by air study; severe mental retardation or other congenital defects, and especially absence of proved progression of the hydrocephalus. The obstructing point is located by studying the flow and absorption of phenolsulfonphthalein after its injection into the lateral ventricle during ventriculography along with a small bubble of air (large volumes of injected air are not well tolerated), and sometimes by dural sinography.

*Treatment* is not generally satisfactory. Two approaches have been attempted: (1) Reduced production of cerebrospinal fluid by plexectomy, fluid restriction, blood letting and the like; these procedures are now largely abandoned. Acetazolamide, orally in large doses, may be effective. (2) The bypass of points of obstruction with shunting of the cerebrospinal fluid to the arachnoid villi or an artificial point of absorption or excretion. In older children with previously adequate subarachnoid systems, third ventricular or aqueductal obstruction responds well to ventriculocisternostomy, either through the lamina terminalis or ambient cistern or by passing a rubber tube from the lateral ventricle to the cisterna magna. In young infants, or when the subarachnoid spaces are obliterated or incompetent, the fluid must be (1) conveyed to a new point of absorption—the lesser peritoneal space is the only satisfactory one, and that for a few months at best—or (2) conveyed from the spinal theca or ventricle to

a ureter, after nephrectomy. The latter shunt is well maintained, but in small infants the loss of cerebrospinal fluid via the urine results in a negative sodium balance and 2 to 3 gm. of sodium chloride must be given daily. Spinal ureterostomy is unaffected by growth; with ventriculo-ureterostomy, longer tubes become necessary as the child grows.

## HYDRANENCEPHALY

In this condition the cerebral cortex, except for the inferior temporal and mesial occipital lobes, is represented only by a membrane filled with clear fluid. The basal ganglia and thalamus are present, the cerebellum and brain stem are well preserved, and the aqueduct is generally obliterated. The size of the head at birth is normal. There are two theories of pathogenesis: (1) It may represent obstructive hydrocephalus in utero, the intrauterine pressure preventing enlargement of the head with resulting cortical atrophy. (2) The internal carotid arteries may be deficient or compressed, allowing only those parts of the brain supplied by the basilar artery to develop. Neither theory is proved, and the condition has been seen associated with cytomegalic inclusion disease. The infant is well formed, but obviously defective and blind, and may have poor temperature regulation. Diagnosis is readily established by transillumination of the head in a dark room (Fig. 325). There is no treatment.

FIG. 325. Hydranencephaly shown by transillumination.

## DEGENERATIVE DISEASES

The outstanding features of the degenerative disorders are functional incapacitation and/or progressive loss of nervous elements. Their etiology is not established, their clinical manifestations are so variable that exact diagnosis during life is difficult, and a satisfactory classification is almost impossible. The following is one of convenience only:

### *Lipidoses, Leukodystrophies and Progressive Encephalomyelopathies*

- A. Cerebromacular degeneration—amaurotic idiocy
- B. Cerebral von Gierke's disease
- C. Demyelinating leukodystrophies
- D. Progressive encephalomyelopathies (Schilder's disease), disseminated sclerosis and neuromyelitis optica

### *Degenerative Disease Involving Specific Fiber Tracts and/or Neural Groups*

- A. Spinocerebellar ataxias—Friedreich's disease and other spinocerebellar forms
- B. Pyramidal degenerations—familial progressive spastic paraplegia
- C. Extrapyramidal disease—dystonia musculorum deformans, Huntington's chorea, hepatolenticular degeneration
- D. Motor neuron disease—Werdnig-Hoffmann's spinal atrophy; the amyotonia congenita syndrome
- E. Neuroradicular disease—peroneal muscular atrophy
- F. Leber's familial optic atrophy

### *Degenerative Diseases of Uncertain Classification*

- A. Cerebral degeneration with myoclonus
- B. Heller's infantile dementia

## LIPIDOSES AND LEUKODYSTROPHIES

Lipidoses and leukodystrophies represent primary disorders in the metabolism of sphingolipids. One or another of these compounds, accumulating in abnormal amounts in the brain, involves the cells and gray matter in cerebromacular degenerations and the white matter with demyelination in the leukodystrophies. Whether this deranged metabolism represents overproduction, underutilization or accumulation of products of degeneration is not known.

### CEREBROMACULAR DEGENERATION

Amaurotic idiocy, or Tay-Sachs disease, is the commonest of the cerebromacular degenerations. It is a degenerative disease of in-

fancy, marked by progressive blindness, macular degeneration, spasticity, seizures, wasting, dementia and death. The lipid involved is ganglioside; one of its components, neuraminic acid, is greatly increased in the brain. The brain is firm and somewhat atrophic; the cerebellum is greatly shrunken. All neurons contain stored lipid. The condition is inherited as a recessive trait, and is most frequent among eastern European Jews. Apparently healthy at birth, the infant by about six months becomes apathetic, shows motor regression and fails to fix with his eyes. At one year he is fat, flaccid and listless, with hyperactive reflexes, and is obviously blind. The classic macular cherry-red spots, which may be black in the Negro, with surrounding gray-white retina, optic atrophy and normal vessels have appeared in the fundi. Next is a stage of intense spasticity, with greatly heightened reflexes, extensor plantar responses, decerebrate posturing and increasing dementia. The infant startles readily at slight sounds. The swallowing function is lost, and, now completely demented, he begins to waste away despite all efforts to maintain nutrition and dies usually before the third birthday. No laboratory procedure is of positive diagnostic value; the usual blood and cerebrospinal fluid determinations remain normal. Serum aldolase rises in the period of active muscular wasting, and serum glutamic-oxalacetic transaminase is elevated throughout. The only important distinction is from Niemann-Pick disease, which may show similar macular and cerebral changes; anemia, foam cells and hepatosplenomegaly distinguish it (p. 1000).

Late infantile and juvenile forms of cerebromacular degeneration also occur. Without racial preference, these are hereditary; the juvenile form is transmitted by both dominant and recessive patterns. The *infantile form* begins about three years of age, often with convulsions followed by ataxia, dementia, spasticity and blindness. There is optic atrophy with or without a red-brown macular discoloration. Death occurs within three to five years. The *juvenile form* begins at a later age with visual failure and fundus changes, including optic atrophy, "pepper and salt" pigment deposits, grayish or brownish discoloration and loss of the foveal reflex at the macula. After a year or two vision is gone or mostly so, and mental changes and seiz-

ures appear, followed by extrapyramidal disorders of gait, explosive laughing or crying, and finally extreme dementia, wasting, contractures and death. Distinction from syphilitic optic atrophy and retinitis pigmentosa is difficult in the first stage; progressive deterioration, seizures and the persistently negative serology soon clarify the situation. If real doubt exists, and the family wish information to guide them in regard to future pregnancies, cortical biopsy may be justified.

#### CEREBRAL VON GIERKE'S DISEASE

Storage of glycolipid or related material in neurons occurs in some instances of glycogen storage disease. The affected infant begins at a few weeks of age to regress in motor performance and alertness, becomes limp, has occasional cyanotic spells and vomits; tachycardia, a large heart without murmurs and thick tongue are present. Cortical blindness, apathy and death follow within the first year. The cerebral and cerebellar cortexes are usually spared, but subcortical neurons and striated (Fig. 326) and cardiac muscle contain material staining for glycogen and with some fat stains. The differential diagnosis includes amyotonia congenita, congenital heart disease, cretinism and mongolism.

#### LEUKODYSTROPHIES

A variety of conditions have been described as "diffuse sclerosis." Genetic patterns, usually recessive, are found in all varieties, and they all have certain histologic features in common. Myelin is destroyed early, and abnormal materials, free fats, cerebroside or metachromatic glycolipids accumulate; oligo-

dendroglial cells disappear and scarring by astrocytes is marked.

The *infantile* or *Krabbe type* has a familial pattern. The infant, well for the first few months, becomes fretful and rapidly apathetic or stuporous; then rigidity is followed by tonic and clonic seizures, vomiting, cortical blindness or optic atrophy or both, dysphagia and wasting. Death usually occurs within a year of the onset. The white matter contains large, globular bodies which take stains positively for glycogen or conjugated glycogen compounds. The disorder involves cerebroside metabolism.

In the *Greenfield type* the onset is in the second year of life with ataxia and loss of reflexes, followed by speech impairment, visual loss, dementia, rigidity and extensor plantar responses. Death occurs about three years of age. The brain shows rather selective destruction of the later-myelinated fiber systems, with pronounced loss of oligodendroglial nuclei and deposits of a material staining strongly for glycolipid complexes and metachromatically with aniline dyes. A later type, strongly familial, begins with disturbance of gait, then mild dementia, pyramidal signs, optic atrophy, and finally rigidity, blindness, convulsions and death, after a period of three to four years. Metachromatic material is present in the brain and kidney, as well as in the urine, where it can be demonstrated by staining with appropriate dyes, making accurate diagnosis in life a possibility.

There is no known treatment for these illnesses. Specific diagnosis is often dependent on a postmortem examination. The most that one can conclude is that dementia, fundus

FIG. 326. Cerebral glycogen storage disease. A, Glycogen- and fat-stain positive material in motoneurons. B, Glycogen-infiltrated skeletal muscle.

changes and seizures which precede outspoken neurologic signs usually indicate disease of the gray matter, whereas milder dementia with more pronounced physical signs and a later onset of seizures suggest primary involvement of white matter.

### PROGRESSIVE ENCEPHALOMYELOPATHIES

*Encephalitis periaxialis diffusa* (*Schilder's disease*) is a progressive disease featured by bilateral spasticity, cortical blindness and deafness, optic atrophy or neuritis, dementia and death. The distinctive pathologic feature is massive destruction of myelin, largely confined to the cerebral hemispheres, with glial scarring and sometimes cavity formation. Arcuate fibers are spared, and neuronal changes are inconspicuous. The disease is hereditary; the onset is at any age, but most commonly is in later childhood. The child has often been vaguely ill, irritable or doing poorly in school for some months before the beginning of clear-cut symptoms. These are usually disorders of gait, due to spasticity, which are often initially hemiplegic, but soon become bilateral. The onset may be almost apoplectic, with either optic neuritis or papilledema; in these circumstances the child is acutely ill, and intracranial pressure may be increased and abducens palsies present. Cortical blindness and deafness (sometimes the initial symptoms) or aphasia and apraxia signify extension into the occipital, temporal and parietal lobes. Mental deterioration always ensues; convulsions may occur late or relatively early in the course. Optic atrophy is common, but cerebellar or spinal cord signs are unusual. Bronzing of the skin is a rare manifestation. The course varies from weeks to a few years.

*Disseminated sclerosis* is a slowly progressive disorder in which recurrent attacks, usually interspersed with remissions, involve various parts of the central nervous system, principally the visual, cerebellar and spinal portions. The lesions are multiple plaques in which there is destruction of myelin, relative preservation of axons, phagocytosis of the products of myelin degeneration and finally glial scarring; wallerian degeneration is inconspicuous. The disease may start as (1) attacks of retrobulbar neuritis; (2) recurrent bouts of paraplegia; or (3) cerebellar disorders with disturbances of gait. Nystagmus, ataxia of speech, emotional lability with euphoria and sphincter disturbances are common. The course is long. During attacks, the proteins of the cerebrospinal fluid, particu-

larly the gamma globulins, are increased, and a paretic gold curve and mild pleocytosis are common. No laboratory finding is diagnostic.

In this form, disseminated sclerosis is rare in childhood. Most cases so diagnosed are perhaps better described as disseminated encephalomyelitis. When it does occur, the common courses are as follows: (1) attacks of retrobulbar neuritis with sudden severe visual loss, central scotomas, loss of color vision and, rarely, swelling of the optic disks. Vision may return after several weeks or may remain permanently defective. In either case the disks become pale, temporally. One or several such attacks may occur and one or both eyes may be involved. During the course of these symptoms or after remissions of months or years, symptoms of spinal cord, cerebellar or cerebral disease appear, usually with weakness of legs, urinary urgency, frequency or incontinence, cerebellar ataxia of a limb and at times hemiparesis. (2) In other instances the onset is characterized by manifestations of partial or fairly complete transverse myelitis, and such attacks may recur repeatedly, often at or near the same site. In this clinical pattern retrobulbar neuritis may, but rarely does, appear later.

Once the course of the illness is established, diagnosis is not difficult. The initial attack of retrobulbar neuritis cannot be distinguished from retrobulbar neuritis of other causes; some believe that all unexplained retrobulbar neuritis is disseminated sclerosis. In Leber's hereditary optic atrophy the central scotomas are usually larger, the loss of vision less abrupt and a familial history usually present. Neuro-myelitis optica, whether of spinal cord or optic nerve, may be indistinguishable. The leukodystrophies are not manifest by evidences of spinal cord lesions, and their course is steadily progressive. Disseminated encephalomyelitis is usually much more violent, the child much more ill, and signs of widespread lesions are apparent.

The prognosis is unfavorable, but long periods of remission are frequent and the outlook is not hopeless. No specific treatment is available. Good nursing care, physiotherapy and especially careful attention to the bladder in acute involvement of the spinal cord are necessary.

*Neuromyelitis optica* is an illness combining visual loss due to optic neuritis with paraplegia due to transverse myelitis. The lesions typically are multiple foci of softening or necrosis in the optic nerves and chiasm and in the white and gray matter of the brain and

spinal cord; the distinction from acute disseminated sclerosis may be largely artificial. The disease occurs at any age. The onset may be with optic neuritis or transverse myelitis, or both. Fever and signs of systemic illness are generally present, especially in the myelitic onset. There is frequently pain and tenderness over the level of the cord lesion, and pain in the eyeball may precede optic neuritis. There is a pleocytosis. At times there may be complete destruction of several segments of the cord and paralysis may ascend rapidly; such patients usually have severe muscular wasting. Such cerebral signs as drowsiness, headache and convulsions are rare.

Differential diagnosis is that of disseminated sclerosis (see p. 1096), which it closely resembles. There is no specific treatment, but since good recovery, for a time at least, is possible, the best of nursing care, tidal drainage of the bladder, respirators for respiratory paralysis and early physiotherapy are indicated.

## DEGENERATIVE DISEASES INVOLVING SPECIFIC FIBER TRACTS AND/OR NEURAL GROUPS

### FRIEDREICH'S ATAXIA

This degenerative disease of unknown cause is transmitted by both dominant and recessive patterns. It is characterized by ataxia, loss of reflexes, pes cavus, kyphoscoliosis, cardiac abnormality, nystagmus and optic atrophy. There is degeneration of the dorsal columns and spinocerebellar and pyramidal tracts, in some lemniscal systems, in the cerebellum and in the optic and auditory nerves.

The majority of cases become symptomatic before puberty. Recessive strains tend to have an earlier onset than the dominant ones. Duration varies from a few to many years, possibly even to a normal life span in incomplete forms; average duration of life is about sixteen years. The first symptoms are ataxia of gait or aching, cramping pains in the limbs. Then clumsiness of hands, truncal ataxia, dysarthria, kyphoscoliosis, nystagmus and optic atrophy appear. The first sign is usually pes cavus with hammer toe deformity, which, combined with absent reflexes, constitutes the commonest pattern of the incomplete forms. The deep reflexes disappear early; distal sensory loss, affecting stereognosis, position and vibratory sense, with little decrease in cutaneous sensation, is common. Ataxia is both cerebellar and spinal in type;

the slapping, reeling gait and the compensatory movements of the trunk and limbs often suggest chorea. The intensity of the voice fluctuates, and the speech is nasal or explosive. Mental retardation is present in about 10 per cent of cases, and progressive dementia is a late event in about the same ratio.

Visceral symptomatology is of especial interest. Vomiting and other gastrointestinal disturbances occur, but the most important are the cardiac symptoms. Tachycardia and loud murmurs are common. The electrocardiogram shows abnormalities of the S-T segment or inversion of the T wave in about half of the cases. Histologically there is a peculiar interstitial myocarditis and fibrosis. Death may be due to a cardiac arrhythmia or congestive failure.

The condition is to be distinguished from other spinocerebellar ataxias and peroneal muscular atrophy with which it may be related, from disseminated sclerosis, especially in older patients, and particularly from rheumatic heart disease with chorea. The last is a common diagnostic error, owing to the ataxic movements, heart murmur, leg pains and electrocardiographic abnormalities. The orthopedic defect and congestive failure are treated symptomatically.

*A number of other forms of hereditary ataxia* have been described in children. These are initially purely cerebellar and later develop pyramidal signs, or they may combine ataxia with spasticity and hyperactive reflexes from the start. A positive family history, a slow course and frequently late visual failure and dementia are common. There is no treatment.

### HEREDITARY SPASTIC PARAPLEGIA

This is a hereditary degenerative disease, with destruction of Betz cells and pyramidal tract degeneration, most prominent farthest from the cortex. Its inheritance is variable, but it is usually recessive and sometimes sex-linked; males are more often affected than females. Symptoms begin usually in early childhood, first as stiffness and slowness in walking, then with steady development of a spastic paraplegia. The reflexes are increased, but Babinski's sign may appear late. The sensory systems, sphincters, upper extremities and the intelligence are spared. Flexion deformities, arrest of growth of the lower limbs, and sometimes late dementia, blindness or other signs occur. The strong familial history usually distinguishes it, but in sporadic cases, tumor of the cord, vertebral disease and other

degenerative or inflammatory lesions must be excluded by examination of the cerebrospinal fluid and roentgenographically with myelography. No curative treatment is known.

#### **DYSTONIA MUSCULORUM DEFORMANS**

Torsion spasm and dystonic movements may occur in several disease processes, such as postencephalitic syndromes and Wilson's disease. There is, however, a fairly distinct clinical entity of maintained torsion of limbs and/or of the trunk of unknown etiology, which occurs mainly in Russian Jews. Pathologically, there is a loss of cells, especially of the large ones, in the basal ganglia. The illness begins before puberty, usually about eight to ten years, without sex preference, but at times with a definite familial pattern. The first sign is a fixed posturing of one leg, the foot extended and held in pes cavus with the toes flexed. Soon the thigh flexes and adducts and the knee bends; then the other leg becomes involved and the child walks on tiptoe. Extreme lumbar lordosis appears early. After some years the arms rotate internally, adduct, extend at the elbows and flex at the wrists. Finally strong involuntary torsion movements appear, which are really a powerful exaggeration of the posturing of legs, trunk and arms; any movement, particularly walking, brings on fantastic writhing. These movements, absent in sleep, are greatly worsened by emotion, suggestive of hysteria, but psychotherapy is not helpful. Reflexes, sensation, sphincters, vision, speech, swallowing and movements of the fingers are not impaired. The condition is distinguished from double athetosis, hepatolenticular degeneration and postencephalitic states by the bizarre picture described, the Jewish parentage, family history and the absence of hepatic involvement or of a history of encephalitis. The course is long, the disease ultimately confining the patient to bed. There is no effective treatment, though pallidotomy has been suggested.

#### **HUNTINGTON'S CHOREA**

This is a degenerative disease of genetic origin (dominant) and is characterized by progressive choreic movements, dementia and death. The brain is atrophic, particularly the frontal lobes; the ventricles are enlarged and there is a widespread, slow degeneration of neurons, greatest in the putamen and in the caudate nuclei. Unaffected members of families have an unusually high incidence of psychopathic or psychotic behavior and suicide. The onset

is usually in the fourth decade, but may occur in children as early as six years, with death by ten years. The first symptom in the child may be an emotional disturbance, choreic movements or seizures. The choreic movements affect the face, trunk and arms at first, the large joints being more involved than the small ones. The movements initially are exaggerations of voluntary ones and tend to remain a crude parody of willed motions. Reflexes are normal or heightened; the cranial nerves at first are intact, but pseudobulbar palsy and swallowing difficulties finally appear. Progressive dementia and the violence of the movements ultimately confine the patient.

Huntington's chorea is distinguished from Sydenham's chorea and congenital chorea principally by its progressive course, dementia and family history; the first and second are, of course, not initially apparent, and the third may be carefully concealed. Hepatolenticular degeneration is excluded by its corneal ring, hepatic involvement and tremor. There is no known treatment, though large doses of rauwolfia derivatives are currently used for reduction of chorea.

#### **HEPATOLENTICULAR DEGENERATION**

##### **(WILSON'S DISEASE)**

This is an inborn metabolic defect, apparently inherited as an autosomal recessive. The symptoms are tremor, dysarthria, hypertonus and dementia, combined with hepatic cirrhosis and corneal pigmentation. Primary failure of formation of ceruloplasmin disturbs copper metabolism; the intestinal absorption and tissue deposition of copper, particularly in the brain and liver, are increased. Plasma copper is decreased and urinary copper increased. The principal anatomic lesions are shrinkage, discoloration or cavitation of the lentiform nuclei and hepatic cirrhosis.

Familial incidence is common. The age at onset is probably determined by the time required for enough copper to accumulate in the brain or liver to produce symptoms; it may vary from seven years to the fourth decade. The duration is usually several years. Indistinct, dysarthric or explosive speech, a fixed unblinking stare, drooling of saliva, tremor at rest and in motion, beginning in a hand but soon involving the entire body, generalized hypertonus, seizures late in the course and dementia are the principal clinical features. Reflexes are altered only by rigidity; sensation remains intact. The characteristic

Kayser-Fleischer ring, usually of golden-brown discoloration at the corneal limbus, and the palpable liver are important signs.

If hepatic symptoms are associated with the neurologic signs, no diagnostic problem exists; if not, Wilson's disease must be distinguished from double athetosis, which is of congenital onset and without real tremor, from dystonia (p. 1098) and from post-encephalitic syndromes. The corneal ring should be looked for with a slit lamp. High urinary and low plasma copper and especially low plasma ceruloplasmin, which otherwise is found only in the newborn or in the nephrotic syndrome, are diagnostic laboratory findings.

Treatment with chelating agents sometimes gives partial, but usually poorly maintained, relief; BAL, Versene and penicillamine have all been tried. Low copper diets, perhaps combined with such agents, may prove to be more effective. Siblings and every case of unexplained cirrhosis or jaundice should be examined carefully to detect early cases.

#### WERDNIG-HOFFMANN DISEASE

This is a progressive hypotonia and wasting of skeletal muscle in infancy and childhood, which is due to degeneration of motor neurons. There is no evidence of other involvement of the nervous system and the condition usually terminates fatally at an early age.

The etiology is unknown. The essential pathologic lesion is progressive loss of motor neurons, with little reaction in the surrounding tissue (Fig. 327, C), beginning or most severe at the caudal end of the spinal cord, extending cranially and finally involving cranial nerve motor nuclei. The anterior roots are thin and pale (Fig. 327, B). The skeletal muscle shows atrophy of denervation as manifest by narrowed fibers, increased sarcolem-

mal nuclei, preserved cross striations and replacement by fibrous tissue (Fig. 327, A). Cerebellar defects and absence or underdevelopment of Betz cells in the motor cortex have been described.

The condition is familial in at least half the cases and may occur in successive generations; its inheritance is not clearly understood, and sexes are equally affected. Fetal movements are often feeble or absent. The infant is born limp, flaccid and areflexic, but sensation, the cranial nerves, sphincter functions and intelligence are adequate. The infant lies in a froglike position and can be folded or doubled into almost any grotesque posture. The muscles are thin, soft and hard to palpate; the only limb movements are feeble flickers of the digits. Side-to-side movements of the head are usually preserved. The intercostal muscles are paralyzed before the diaphragm, resulting in sternocostal retraction and respiratory difficulty. Fibrillations of the tongue appear, sucking is lost and the infant usually dies of respiratory infection by eight to twelve months of age.

Variations in the time of onset or the rate of progression are common. *Arthrogryposis multiplex congenita* may represent an incomplete form which has run its course in utero. By contrast, fetal movements may have been present, and the infant at birth appears to be normal, only to manifest the illness in the first few days or weeks. In other instances the symptoms may not appear for several months or even a year or two. Sometimes the progress is slow, growth for a time outstrips degeneration, and the infant slowly makes some developmental progress; a few may live for years, but seldom to puberty.

Werdnig-Hoffmann disease is one of the many entities comprising the *amyotonia congenita syndrome*, which in actuality only im-

FIG. 327. Werdnig-Hoffmann disease. A, Fascicular atrophy of muscle. B, Pallor of ventral roots. C, Degenerating motoneurons.

plies extreme hypotonia in an infant. Other causes include the following:

1. Diseases of the central nervous system or neuromotor unit
  - Atonic diplegia
  - Cerebral lipidosis
  - Cerebral von Gierke's disease
  - Kernicterus
  - Neonatal poliomyelitis
  - Infantile polyneuritis
  - Spinal cord lesion birth injury or congenital tumor
  - Congenital or neonatal myasthenia gravis
  - Congenital myopathies
  - Polymyositis
2. Non-neurologic diseases
  - Deficiency states such as rickets and scurvy
  - Chronic infection
  - Malnutrition
  - Congenital defects, such as arachnodactyly
3. Benign congenital hypotonia

*Differential diagnosis* of the syndrome can be difficult. The diagnosis of Werdnig-Hoffmann disease depends on (1) a history of familial incidence and diminished or absent fetal movements; (2) the presence of extreme hypotonia and areflexia in an otherwise normal infant at or soon after birth or development of weakness and hypotonia in an infant or young child; (3) generally normal laboratory studies, except for muscle biopsy and perhaps electromyography. The infant with atonic diplegia may be exceedingly limp, but the reflexes are retained; there is often a history of abnormal pregnancy and labor, the infant makes powerful spontaneous movements at intervals, and signs of mental retardation soon become obvious. The cerebral degenerative diseases, lipidoses and cerebral von Gierke's disease may parallel Werdnig-Hoffmann's disease in time of onset and general flaccidity, but the reflexes are retained and the progressive loss of vision and dementia are distinctive. A history of unusual neonatal jaundice and early athetoid movements distinguishes kernicterus. Neonatal poliomyelitis is best excluded by serologic studies, and infantile polyneuritis by an onset following intestinal or respiratory infection and by a maintained high cerebrospinal fluid protein level. Birth injury of the spinal cord regularly complicates breech delivery; the segmental pattern of motor and sensory paralysis, sphincter involvement and loss of sweating in the involved area are characteristic; a segmental level of paralysis may also be due to a congenital spinal cord tumor. Neonatal myasthenia affects only the infant of a myasthenic mother; as in congenital myasthenia

there is early involvement of ocular and bulbar muscles and a diagnostic response to Prostigmin. Congenital myopathies or polymyositis may require muscle biopsy to distinguish them.

Of the non-neurologic diseases, the pseudo-paralysis of scurvy may superficially resemble Werdnig-Hoffmann disease, but distinction is not difficult (p. 368) as is the case with rickets (p. 375). The infant with arachnodactyly may have hypotonia, but other features are diagnostic (p. 1243).

The most important differential diagnosis is with the syndrome of *benign congenital hypotonia*, which at times is familial. The infant usually has moved well in utero; some tendon reflexes can always be obtained, and no other neurologic signs are present. Despite striking hypotonia and hypermobility of joints, the child occasionally makes strong movements. Sternocostal retraction and respiratory distress occur, but evidence of progression or fibrillations of the tongue do not appear. Physical milestones are passed slowly, few walk before eighteen and twenty-four months of age, and many not until three to five years. Ultimately all are able to get about and about half of them are quite normal by eight or nine years of age. In others the muscles remain feeble, and then may develop contractures, but the joints always remain hypermobile. Muscle biopsy reveals no abnormalities. Treatment is limited to orthopedic assistance in the avoidance of contractures.

#### PERONEAL MUSCULAR ATROPHY

##### (CHARCOT-MARIE-TOOTH'S DISEASE)

Peroneal muscular atrophy is a hereditary disease characterized by distal wasting, weakness, and loss of reflexes in the extremities.

Pathologically, there is degeneration, apparently first in the motor nerves, then in the roots with some loss of motor cells. Similar changes appear later in the sensory nerves and dorsal root ganglia, and secondary degeneration extends up the dorsal columns. The muscles involved show atrophy of denervation.

The disease is strongly hereditary by dominant, recessive or sex-linked recessive patterns. Symptoms generally begin in late childhood or adolescence; progress is slow, and the disease is compatible with long life. Wasting, first of the extensors, evertors and intrinsic muscles of the feet, produces the dropped foot and equinovarus deformity; the peroneal, tibial and finally the calf muscles are involved, but wasting seldom goes much above

the knee, thus producing the characteristic storklike leg. Loss of muscular strength parallels loss of bulk, and fasciculations are usually present. The ankle reflexes disappear, but the patellars persist. Cramps and paresthesias may be present early, but sensory loss is slight, involving mostly positional and vibratory senses. Similarly, wasting and sensory and reflex losses later involve the forearms. Sphincters are not often affected; optic atrophy may occur late. The extremities are cyanotic, cold and mottled; after years, atrophy of bones and perforating ulcer of the foot appear. Incomplete forms, especially claw foot with absent ankle jerks, are common.

The cerebrospinal fluid is usually unchanged, and no laboratory finding is diagnostic. Familial incidence, slow course and absence of muscle tenderness distinguish it from chronic polyneuritis; absence of ataxia, nystagmus, widespread reflex loss and cardiac findings, from Friedreich's disease. Interstitial hypertrophic polyneuritis is characterized by miotic, fixed pupils, increased cerebrospinal fluid protein, and palpable peripheral nerves, none of which are present in peroneal atrophy. The disability is surprisingly slight in view of the wasting. Braces and fusion of ankle joints keep the patient ambulatory.

#### HEREDITARY OPTIC ATROPHY

##### (LEBER'S DISEASE)

Leber's disease is a hereditary degeneration of the retina and papillomacular bundle with serious loss of vision; at times there are associated neurologic symptoms. The ganglionic and, to a less extent, the inner nuclear layers of the retina are degenerated, and the axons and myelin sheaths of the papillomacular bundle are destroyed without inflammatory response, whereas the peripheral fibers are partially spared. There is transneuronal degeneration in the lateral geniculate bodies and in the optic radiation. The remainder of the brain is normal.

The condition is usually inherited as a sex-linked recessive, appearing in males, but dominant strains and occurrence in females are known. The onset is usually in the late teens, but may be in childhood or adult life. Rapid loss of vision—sometimes beginning in one eye, but soon becoming bilateral—large, absolute central scotomas and relative peripheral scotomas accompany mild swelling of the disks, which is replaced by pallor in a few weeks. The rest of the fundus is normal. Vision fails rapidly for a few weeks, then be-

comes stationary and remains so for years. Complete blindness is rare. Associated neurologic manifestations, such as epilepsy, ataxia, club feet, mental deficiency and sphincter involvement, are not uncommon. The family history, rate of onset, bilateral visual loss and large scotomas usually distinguish it from retrobulbar or optic neuritis. There is no treatment.

#### DEGENERATIVE DISEASES OF UNCERTAIN CLASSIFICATION

##### HELLER'S DISEASE

This singular illness is a progressive dementia without other signs of organic neurologic disease. Pathologic data are scanty; sclerotic, irregularly arranged cortical neurons, lipid deposits, meningeal fibrosis and multinucleated giant glial cells have been described, though none is completely convincing. The onset of illness is in the third or fourth year of life. A child, previously well or perhaps after an infection, first becomes irritable and disobedient, has temper tantrums, and then begins to regress in speech and signs of mentation. Within a year he is mute, pays no attention to speech, may have tics, is incontinent and often has to be fed. All observers stress the intelligent expression which is said to persist, though the behavior is that of extreme dementia. The patients survive for years. It is still uncertain whether this is an organic disease in the strictest sense, or a form of schizophrenia in childhood (see Autism). No treatment has been effective.

#### THE SYNDROME OF EPILEPSY, CEREBRAL DEGENERATION AND MYOCLONUS

The association of seizures, myoclonic jerks and cerebral degeneration is not uncommon in childhood. Two forms are recognizable and may represent the same disease.

In the first, often familial and probably hereditary, lesions consist in degeneration and necrosis in the middle and outer cortical layers, producing status spongiosus and some gliosis. The deeper cortex and white matter are spared, but similar lesions are present in the thalamus, lentiform nuclei and the dentate and olivary nuclei. Infantile and juvenile types occur. In infancy the onset is with head-dropping spells, myoclonic jerks of trunk

and arms, and generalized seizures (see also p. 1119). Rigidity and some ataxia appear, the child demented rapidly, seizures begin to occur in bouts, and myoclonic jerking is almost constant. Cortical deafness and blindness without optic atrophy appear early. The child dies in status epilepticus after one or two years. The *juvenile form* begins in early childhood, the child sometimes having been previously retarded. The progress of signs and symptoms, though slower, is like that of the infantile form; choreo-athetosis and cerebellar signs are usually more conspicuous. Death in status epilepticus occurs after several years.

The second form, *Unverricht's myoclonus epilepsy*, is a hereditary disease, probably recessive, characterized by convulsions, massive myoclonic jerks, ataxia or choreo-athetosis and dementia. Intracytoplasmic inclusion bodies in neurons and degeneration and gliosis of the outer cortical layers are charac-

teristic pathologic features. The onset is prepuberal, and the first symptom is a convulsion. Minimal cerebellar ataxia or extrapyramidal signs and myoclonic jerks are usually present, but often overlooked. In succeeding years the child becomes irritable and regresses mentally. As dementia slowly increases, the convulsions disappear and are replaced by massive myoclonic jerks involving the shoulders, trunk and proximal parts of the limbs. They are so violent that they prevent walking, ultimately confine the patient to bed and may conceal the evolution of cerebellar and extrapyramidal signs.

The family history, progression, frequency of extrapyramidal or cerebellar signs, myoclonus and replacement of seizures by massive myoclonus separate these illnesses from the common occurrence of myoclonic jerking in epileptics. No treatment is known other than the use of anticonvulsants for symptomatic relief.

## NEUROLOGIC SYNDROMES PECULIAR TO CHILDHOOD

The following illnesses seem the almost exclusive property of childhood. Syndromes rather than diseases, they are encountered frequently enough to deserve mention.

### SPASMUS NUTANS

This condition, also called nodding spasms, which is found mainly in infants, combines irregular movements of one or both eyes, head-nodding and deviations of the head. The etiology is unknown. Vitamin A or D deficiency, wasting illness and in particular poor lighting of nurseries, which might delay development of optic fixation, have all been suggested. The disease is more common in the low-income group, and symptoms usually begin in the winter, but convincing evidence for any of the supposed etiologies is wanting.

The onset may be as early as a few weeks or as late as three years, but most often is between four and twelve months of age. There is no sex preference; more than one sibling may be affected. The three cardinal symptoms are head-nodding, irregular eye movements and deviation of the head. Movements of the head or eye may be the first or the only symptoms. Head movement occurs

in about 80 per cent of cases and perhaps is the most common initial symptom. It is slow, inconstant and irregular and occurs in any direction; it disappears during sleep or when the child lies down. Eye movements, which also occur in about 80 per cent of cases, usually begin in one eye and are almost always more pronounced in one than in the other. They are rapid, inconstant, irregular jerkings of small amplitude in any direction and without definite components. They disappear when the eyes are covered or the child sleeps, but are instigated or made worse by holding the head still. Deviations of the head, which occur in about one third of cases, are in any direction and do not lead to contractures; they may help the child to focus. Nonparalytic strabismus occurs at times; there are no other ocular or neurologic signs. The condition clears spontaneously, usually within several months. At times there are temporary exacerbations.

*Congenital nystagmus* is differentiated from spasmus nutans by the family history, early onset, compensatory head movements and failure to improve. No treatment of spasmus nutans is necessary beyond ensuring adequate light and nutrition and reassuring the parents.

## ACUTE CEREBELLAR ATAXIA

Cerebellar syndromes after infections are not uncommon; measles and chickenpox are known precursors. Many cases of acute ataxia in childhood, however, have no apparent cause, and, since they are seldom fatal, the pathologic lesions are not known. The syndrome is commonest in young children who have begun to walk, usually between two and four years of age. There may be no history of previous illness, or only a slight cold. The onset is usually rather sudden. The child may vomit occasionally for a day or so; the principal feature is the evolution over a few hours to three or four days of a decided unsteadiness of gait; the child often refuses to walk or even to lift his head. Some irritability or change in personality is present, but convulsions, stupor or signs of systemic illness are usually absent. Physical signs include unsteadiness, wide-based gait, cerebellar ataxia, heightened or depressed reflexes, hypotonia and fugitive extensor plantar responses. Irregular or rapid jerking of the eyes, when the child attempts to fix, is common. The cerebrospinal fluid at the onset is normal or contains a few lymphocytes; after days or weeks the protein may rise to 200 mg. per 100 ml. or more. Beyond a mild peripheral leukocytosis and variable electroencephalographic abnormalities in about half the cases, no other laboratory tests are abnormal. The unsteadiness and irritability may persist for weeks or months, but usually disappear completely; residual disability is rare.

Such cases must be differentiated from brain tumor, cerebral degenerative diseases, poliomyelitis and the early stages of polyneuritis. Absence of increased intracranial pressure and the course of the illness are the most valuable differential points. Tumor or degenerative disease inevitably advances, the former with signs of increased intracranial pressure, localizing signs or both. Facial diplegia, distal sensory loss and usually complete areflexia distinguish polyneuritis. There is a possibility that the condition represents cerebellar involvement by any of the various encephalitic viruses or perhaps by a variety of toxic agents. The treatment is entirely symptomatic.

## ACUTE INFANTILE HEMIPLEGIA

(POLIO-ENCEPHALITIS OF MARIE-STRÜMPPELL)

This syndrome of hemiplegia with lateralized seizures and usually severe neurologic re-

siduals has a sudden onset. The etiology is almost certainly manifold. Thrombosis on subintimal plaques in cerebral arteries, thrombosis of the carotid artery, embolism of unidentified source, intracerebral rupture of vascular anomalies and cortical thrombophlebitis are all possibilities.

In the classic form a child of one to two years of age, previously well except perhaps for a slight cold, begins his illness with the apoplectic onset of lateralized seizures, often with a jacksonian type of progression. Between seizures the affected limbs are flaccid and hemiplegic. The child is comatose and soon has fever and some leukocytosis. Meningeal signs are absent and there are usually no changes in the cerebrospinal fluid at this time. The electroencephalogram shows principally voltage depression or absence over the affected hemisphere. No pathogens are consistently cultured.

Coma persists for hours or days, but the child seldom dies. Cells appear in the cerebrospinal fluid after some days, probably as a reaction to necrotic tissue. Movement slowly returns to the affected side, first in the extremity last involved by seizures. Walking and, especially with right hemiplegias, talking must be learned again. The neurologic residuals include (1) hemiparesis, in about three quarters of the cases, with growth arrest and often choreo-athetoid movements of the affected side; (2) recurrent lateralized seizures in about two thirds—they may worsen the hemiparetic signs transitorily; (3) intellectual disturbances in about three quarters, ranging from learning disorders to severe mental deficiency. Hemianopsia is infrequent. Second attacks are almost unknown.

In the acute stage, pneumoencephalography may show swelling of the affected hemisphere and shift of the ventricles; later there is obvious dilatation of the involved lateral ventricle and lateralized cortical atrophy. The skull grows asymmetrically, the vault on the affected side smaller, the bone thicker, the petrous ridge higher and the frontal sinus larger than those on the unaffected side.

This condition must be distinguished from meningitis, encephalitis and hemorrhagic encephalopathies by persistent lateralization of the signs and normality of the cerebrospinal fluid in the early stage. Tumors and abscess lack such apoplectic onset and cause increased intracranial pressure. Occasionally a severe bout of convulsions may call attention to or worsen a hemiparesis of congenital

origin, previously undetected, and cause some confusion.

In infants, usually under one year of age, hemiplegias and seizures occasionally occur during severe respiratory and intestinal infections. These infants are gravely ill; it will often be found that their signs are bilateral, but more notable on one side. Pleocytosis of the cerebrospinal fluid appears early. These cases probably represent cortical thrombophlebitis or extensions of thrombosis from dural sinus occlusions into the cortical veins. In older children the onset may be slower with recurring attacks of numbness or weakness of an arm, leg or entire side over a period of hours or days before a persisting hemiplegia develops. Some of these have been proved to be due to thrombosis of the carotid artery in the neck.

**Treatment.** In the acute state, treatment consists in sedation or rectal anesthesia to control seizures, fluids, treatment of any infection present, avoidance of secondary infection and possibly hypothermia. Since endarterectomy may improve the prognosis for carotid thrombosis, any atypical case should have arteriograms performed within the first few hours; if obstruction is found, immediate surgical removal of the clot should be attempted.

In chronic cases physiotherapy and special schooling for the handicapped are necessary. Seizures are so frequently a residual that an anticonvulsant drug should be given routinely. Rarely, intractable seizures or behavior disorders at later ages may benefit by hemispherectomy.

## CRANIOCEREBRAL AND SPINAL TRAUMA

The symptoms of a blow on the head are due mainly to differential movement of the brain and skull. Brief loss of consciousness is caused either by the effect of a sudden shift of intracranial contents on the hypothalamus and periaqueductal gray matter or by less-understood direct effects on nerve cells. At points where shifting of the brain brings it against the skull, multiple hemorrhagic foci or wedges of cortical necrosis appear; these lesions, with some swelling of the brain, may produce moderately prolonged unconsciousness and mild neurologic signs. Severe swelling of the brain or intracerebral hematoma compresses large vessels, damages widely distant parts of the brain and causes prolonged unconsciousness and localizing neurologic signs.

In open head injuries the skull and dura are lacerated. The child is usually unconscious and in shock, with localizing signs. Such an injury is a grave surgical emergency, requiring immediate treatment of shock and débridement of the wound. Most head injuries of childhood are closed ones with or without fractures; operation is indicated only when there is suspicion of epidural, subdural or intracerebral hematoma (p. 1087).

**Mild Closed Injury.** The usual history is that after a fall the child was unconscious for a few seconds, then seemed pale and shaken or screamed lustily, and two to four hours later became sleepy and vomited. He was irritable and drowsy and his pulse was

a little slow, but neurologic signs were absent. The management is careful, repeated observation of vital and neurologic signs to detect possible development of intracranial hypertension. A roentgenogram of the skull should be obtained, if convenient, and the child put in a quiet room where pulse, respirations, blood pressure, state of consciousness, size and reactivity of pupils and appearance of any neurologic signs are recorded every half-hour for four hours. If no change occurs, observation of pulse, respirations and state of consciousness is continued at home, the child being awakened at least every two hours to make sure that he is not drifting into stupor. Recovery is usually complete in twelve to twenty-four hours.

**Severe Closed Injury.** The child is usually stuporous or unconscious, though seldom in deep shock, which, if present, should lead to search for other injuries. A patent airway should be ensured at once by tracheotomy, if necessary, and shock, if present, should be treated. A sequential record is begun of vital signs, state of consciousness, pupillary size and reactions and such lateralizing neurologic signs as diminution of spontaneous or induced movement and appearance of Babinski's sign. Since such signs often fluctuate, it is the establishment of a trend in one or another direction, rather than isolated observations, that is important. Rising blood pressure, slowing pulse and respiration and deepening stupor mean increasing pressure; if

lateralized pupillary dilatation or motor signs appear, intracranial hematoma must be sought for.

Intravenous fluids should be given cautiously, glucose in 0.45 per cent saline solution being safest; oral or stomach tube feeding should be started as soon as possible. Fever, often due to the injury alone, responds to aspirin, sponging, and cooling by fans or air conditioners. Lumbar puncture is not generally advisable, but may help to control restlessness, for which paraldehyde rectally is also valuable. Opiates and mydriatics should not be used. Infection or suspicion of a basal fracture is an indication for antibiotic therapy.

Controlled hypothermia, the child being cooled to 90° to 92° F. and so maintained for about five days, is now frequently used; it may have some benefit.

The presence or absence of *skull fracture* seldom changes the management. A linear fracture across a suture or a diastatic fracture in the infant increases the possibility of epidural hematoma. A depressed fracture in a newborn infant should be elevated as soon as discovered; in older children elevation is deferred until edema subsides. A basal fracture is probably present if there is (1) bleeding from the nose, ears, pharynx or bilaterally into the orbits; (2) a peripheral facial palsy; or (3) escape of cerebrospinal fluid from the nose or ear. Antibiotics should be given to such patients routinely, and the meningeal fistula closed surgically.

*Post-traumatic syndromes* include epilepsy, psychotic states and neuroses. Epilepsy follows closed head injury in about 3 per cent of cases, open head injury in as many as 50 per cent; it appears to be related to the site and nature of the injury. Its onset cannot be predicted by post-traumatic electroencephalographic abnormalities unless they become paroxysmal. The seizures are almost always controllable by drugs. The child recovering from an open injury or a severe closed one should be maintained on anticonvulsant therapy for at least one year.

Postacute psychotic states are rarely per-

sistent. Neuroses, headache, giddiness, fatigability, poor concentration and behavior disorders are not uncommon. Malingering, unless fostered by parents, is rare. Encouragement, reassurance and optimism on the part of the physician and parents are the best prevention and therapy.

**Injury of the Spinal Cord.** Much rarer, but more crippling than head injury, spinal cord trauma is almost always associated with fracture or dislocation of vertebrae. In breech delivery excessive traction on the trunk before the aftercoming head is delivered is a cause of severe injury; a distinct snap may be heard. The lesion is a fusiform, central hemorrhagic necrosis in the lower cervical and upper thoracic cord; at times there is actual severance. The infant is paraplegic below the lesion, and there is urinary retention. Roentgenograms of the vertebral column usually show no lesion. Such an injury may be confused with congenital defects of the cord or with amyotonia congenita. The mortality is high. In those who survive, recovery of function is insignificant, and arrest of growth occurs below the lesion. Only supportive treatment is possible.

In the older child falls, blows or diving accidents are common causes of cord lesions; the usual sites are C 5–6 and T 12–L 1. Paraplegia is usually complete at first with sensory, motor and sphincter paralysis; tendon reflexes below the lesion are absent for some days. Physical and roentgen signs of fracture or dislocation are usually present. The child should be immobilized, from the moment of injury if possible, to prevent further injury; all movement of the vertebral column should be carefully avoided. Casts, hyperextension and traction are used for simple and compressed fractures; laminectomy is indicated only for comminuted fractures. High cervical lesions may require a respirator; tidal drainage of the bladder maintained until voluntary or automatic control returns and scrupulous care of the skin are essential. The return of function is usually poor.

## DISEASES OF THE SPINAL CORD

The spinal cord suffers with the rest of the nervous system in most neurologic disease. A few conditions, however, require special mention. Nuclear aplasias and localized developmental defects may affect any motor

nucleus, in which case the muscle supplied is small or absent. Nuclei for the anterior abdominal muscles and for parts of the pectoral muscle and, in the brain stem, the facial and abducens nuclei are common sites. Defective

development of preganglionic autonomic centers or more widespread congenital malformations may be associated.

In *syringomyelia* a tubelike cavity develops within the spinal cord, initially in the lower cervical portion, from which it extends downward or upward. A similar slitlike cavity in the lower brain stem is termed *syringobulbia*. The process of cavity formation destroys parts of the anterior and posterior horns, commissures and fiber tracts. The cause is unknown, but faulty fusion of alar and basal plates or trauma from repeated neck bending may be contributing factors. *Platybasia*, *dolichocephaly*, sternal deformity, *spina bifida*, *kyphoscoliosis* and spinal cord tumors may coexist.

Symptoms begin in the second or third decade. Weakness and wasting of the hands or arms, lack of cognizance of burns or other trauma to the arms and shoulders, shooting pains in the upper limbs, stiffness of gait and finally urinary urgency and frequency are common. The signs are wasting and loss of reflexes of the hands and forearms, spasticity and pyramidal signs in the legs and varying degrees of sensory loss over the involved dermatomes; incomplete syndromes are frequent. *Syringobulbia* produces lower cranial nerve palsies and facial and corneal analgesia.

The cavity, if under tension, may erode vertebral pedicles or cause spinal block. A spinal cord tumor must be excluded for which laminectomy or a myelogram may be necessary. There is no satisfactory treatment; decompression of the cavity and roentgen therapy are thought to check its progress, which is usually slow and may arrest spontaneously.

Symptoms of *compressing lesions of the spinal cord* depend partly on the rate of development of pressure. Slowly advancing pressure produces spasticity, weakness and faulty gait with pyramidal signs; sensory loss and urinary urgency and incontinence come later. Rapidly advancing pressure causes sudden paraplegia, with urinary retention and areflexia. Stiff back or neck, radiating root pain, which is worse after lying down or on coughing, percussion tenderness over the site of the lesion and local muscular atrophy are other signs. Lesions of the cauda equina and conus produce overflow incontinence from the start.

Common causes of spinal compression are congenital vertebral defects, collapse of vertebral bodies from metastases or osteomyelitis

or expanding lesions such as cysts, abscess or tumor. Young children with severe pharyngitis may have severe stiffness of the neck and mild paraplegia; hyperemia and softening of supporting ligaments may permit spontaneous dislocation of the cervical vertebrae without osteomyelitis. Intervertebral disk protrusion is rare in childhood and follows direct trauma.

*Intraspinal abscess*, almost always epidural, may be secondary to a remote infection or may be a direct infection through a dermal sinus or from a neighboring osteomyelitis. Spinal cord compression develops rapidly, and percussion tenderness over the lesion is exquisite, but signs of infection need not be present. Immediate surgical decompression is indicated to relieve the spinal block. Careful attention to the bladder and the paralyzed extremities is imperative, since recovery is usually possible when the pressure is relieved early and urinary tract infection or trophic sores avoided.

*Spinal cord tumors*, about one fifth as common as intracranial ones, include epidermoids, lipoma, teratoma, ependymoma, neurofibromas on roots or centrally placed, and metastases usually from lymphomas or medulloblastomas. The symptoms are those of slow spinal cord compression with stiff back, root pain and localizing signs; the clinical course may be irregular and rapid. Papilledema is a rare and unexplained sign. Myelography will usually establish the diagnosis. All such lesions should be explored.

*Cysts* are either dermoids or epidural; the latter, in adolescent boys, may produce the syndrome of *kyphosis dorsalis juvenilis*.

*Transverse myelopathy* is a syndrome which may be part of a demyelinating disease or result from vascular occlusion or from rupture of vascular anomalies. It may occur in association with infections or immunizations, when it is probably due to vasculitis as a manifestation of hypersensitivity. The illness usually starts with fever, stiff neck and pains in the back or extremities; the signs of a transverse lesion of the cord evolve over hours to a few days. Cerebrospinal fluid protein is increased, pleocytosis may be present, but spinal block is rare. All degrees of severity may occur. Poliomyelitis is excluded by sensory loss and sphincter involvement; epidural abscess, by absence of spinal block. Recovery may be complete, or there may be any degree of residual paralysis. There is no specific treatment. Skilled nursing care is essential. Corticosteroid therapy has been used.

# DISEASES OF THE AUTONOMIC NERVOUS SYSTEM

Symptoms of abnormal autonomic function are common to many neurologic diseases, but proved primary dysfunction of the autonomic system is rare. Congenital defects occur in Hirschsprung's disease, in which the intrinsic plexuses of the gastrointestinal tract are aplastic, and possibly in some congenital defects of the urinary tract; autonomic centers in the spinal cord, as well as in peripheral ganglia, may be defective.

*Familial dysautonomia*, the Riley-Day syndrome, occurs mostly in Jews. The constant features are defective or absent lacrimation and corneal sensory impairment leading to corneal ulceration; episodic hypertension and postural hypotension; blotchy skin and hyperhidrosis; generalized indifference to pain; mental and physical retardation; impaired

temperature regulation and feeding problems in infancy. The children are small, emotionally unstable, hypotonic, hyporeflexic or areflexic and poorly coordinated. They swallow poorly, salivate excessively, drool, and have urinary frequency. Recurrent respiratory infection is common. No adequate pathologic basis is known, though disseminated lesions in the reticular formation of the brain stem are described. The diagnosis is a clinical one, based on the signs and symptoms described. Treatment is limited to supportive therapy during hypertensive or vomiting crises, protection of the cornea, use of sedative and ataractic drugs and efforts to maintain a good emotional equilibrium. Some children may reach adult life.

## NEURITIS AND NEUROPATHIES

Degenerative changes in peripheral nerve, plexus or root have many etiologies. Mechanical injury usually involves single nerves or parts of plexuses; chemical, metabolic or toxi-infective substances are more likely to cause generalized damage. The pathology in most cases is similar, comprising breakdown of myelin sheath, proliferation of sheath cells, some invasion by phagocytes and often degenerative change or disruption of axons; true inflammatory changes are slight. In recovery axons remaining intact reinvest with myelin, while those actually degenerated must proliferate from the proximal stump; regeneration is always more complete if physical continuity of the nerve trunk is maintained.

### CHRONIC POLYNEURITIS

This is a syndrome with a clinical pattern like that of acute infective polyneuritis (Guilain-Barré syndrome, p. 525), except that it may continue for several years. Occurring in infancy, it is frequently mistaken for Werdnig-Hoffmann disease, from which it is distinguished by a high cerebrospinal fluid protein content, a mild sensory loss and protracted recovery over years.

### POLYNEURITIS DUE TO CHEMICAL, METABOLIC AND TOXI-INFECTIVE AGENTS

Polyneuritis due to heavy metals, such as lead and thallium, is rare in childhood and usually accompanied by an encephalopathy which dominates the picture. Serum sickness following the injection of almost any foreign protein may cause a generalized polyneuritis or an isolated lesion of a peripheral nerve or plexus, usually of the fifth and sixth cervical roots. These lesions are independent of the site of the injection. Muscular atrophy may be severe and permanent, though the prognosis is usually good. Deficiency states, pellagra, porphyria, primary amyloidosis and certain drugs are also occasional causes.

Polyneuritic and sometimes mononeuritic manifestations occur in many infections of childhood, notably in scarlet fever, typhoid fever, dysentery and mumps. In diphtheria neuritic signs tend to appear in three stages: palato-pharyngo-laryngeal paralysis in the second week of the disease, paralysis of accommodation in the third week and, in the second month, generalized polyneuritis. The last reaches its peak after eight to ten days and recedes slowly over several months.

**TRAUMATIC NEURITIDES**

These are due to direct injury to nerve trunks or to transmitted injury through pressure, edema or scarring. Almost any nerve may be affected; the common groups are (1) obstetric palsies; (2) neonatal facial palsy, and Bell's palsy; (3) palsy due to pressure, laceration or to trauma from injection; (4) palsies due to neoplastic invasion.

**OBSTETRIC PALSY**

See page 318.

**NEONATAL FACIAL PALSY**

See page 320.

**BELL'S PALSY**

Sudden peripheral facial palsy in childhood is identical with that in the adult, weakness being preceded frequently by otitis or exposure to cold; the side of the face is often numb or prickly for a day before paralysis ensues. Pathologically, swelling, congestion and constriction of the nerve in the facial canal are the principal findings.

Bell's palsy is sometimes confused with the early development of facial diplegia in polyneuritis, with bulbar poliomyelitis or other viral involvement of the facial nucleus or with herpetic lesions of the geniculate ganglion. True Bell's palsy is rare under two years of age; facial palsy in this age group should rouse suspicion of one of the above or, more ominously, of tumor of the brain stem.

More than 80 per cent of patients with Bell's palsy make a good recovery if an existing otitis is adequately treated; no other treatment is indicated except for protection of the cornea and perhaps adhesive strapping of the face to avoid stretching of facial muscles during recovery. Corticosteroids, started within the first forty-eight hours, are thought by some to reduce edema and improve recovery. Almost all patients maintain some slight asymmetry throughout life and may have persistent misregenerative movements: blinking the eye when the lips are smacked or twitching the corner of the mouth when the eyes are blinked.

**PALSIES DUE TO PRESSURE OR LACERATION**

Maintained pressure on a nerve trunk interrupts function and ultimately continuity of axons. A poorly placed cast or intravenous board, careless positioning of limbs in anesthetized children and pressure of knapsack straps are common causes. Recovery from such palsies is spontaneous and complete, usually requiring one to four months. Simple pressure

palsies need only support of the involved limb in the position of rest and passive exercise. Lacerations or severances, caused by cuts or at fracture sites, require careful surgical suture. Unless the original cut was a clean one, reparative surgery is best delayed four to eight weeks, since the full extent of destroyed nerve is usually greater than it originally appears. Premature suture may end in ineffective regeneration and formation of a neuroma.

Palsies due to injection of serums and antibiotics deserve special attention. Sciatic and radial nerves are usually involved. Damage is due apparently to direct trauma and to pressure from secondary scarring, rather than to specific toxicity of the injected material. Complete wrist drop usually marks the radial palsy; in sciatic lesions the peroneal division suffers most, and foot drop and peroneal sensory loss are often the only signs. Sharp pain is instantaneous, but weakness may occasionally be delayed for some days; both are often overlooked in the young infant. A fair degree of recovery is the rule, but sciatic injuries in young infants usually arrest growth of the foot. Surgical dissection of scar from the nerve may be of some avail, though its beneficial effect is not proved.

Signs of isolated or multiple root or nerve lesions may be caused by a neoplasm, especially of the pelvis or abdomen. Unexplained persistent weakness, pain, sensory loss or decreased reflexes in the legs should provoke search for such a neoplasm. Another singular variety is a transient radial palsy caused by an overlying mass of subcutaneous fat necrosis in a newborn infant.

# Tetany

Tetany is a syndrome whose principal manifestations result from a state of increased neuromuscular irritability. Because of its occurrence in a number of unrelated conditions, it has seemed expedient to describe the more important types under their respective designations. They are brought together here as an aid in the differential diagnosis of the various conditions in which tetany may be one of the manifestations. The differential data are summarized in Table 108.

The clinical forms of tetany can be divided into two groups: those caused by a decrease in serum calcium, and those associated with a state of alkalosis. Tetany has also been attributed to certain intoxicants, notably guanidine.

Tetany can be produced experimentally in animals by intravenous administration of phosphate. Serum calcium is lowered after injection of either the acid or the alkaline salt, but tetany occurs only after administration of the alkaline phosphate. It is assumed that the acid salt increases the relative concentration of the ionized calcium, whereas the alkaline salt reduces it. It is estimated that under usual conditions slightly more than 50 per cent of the serum calcium is in a diffusible state and that the remainder is non-diffusible, being bound to serum protein. Practically all the diffusible calcium is ionized; only a small fraction is present in the form of a citrate-like compound.

It is the increase or decrease of the diffusible or ionized serum calcium which is responsible, respectively, for the symptoms of hypercalcemia or hypocalcemia. Thus for a proper evaluation of a serum calcium determination the serum protein level should also be known, since, even when the total serum calcium is within the normal range, the ionized fraction may be increased or decreased, depending upon the level of the serum protein. Nephrosis provides an example. Owing to the low serum protein levels, total serum calcium may be reduced below the tetany level of 6 to 7.5 mg. per 100 ml. without clinical manifestations of tetany be-

cause there remains an adequate concentration of ionized calcium. Conversely, the serum ionized calcium could be so increased in such a case by hyperactivity of the parathyroids or administration of parathyroid hormone that the relative increase in ionized calcium would actually constitute hypercalcemia, even though the total serum calcium was not above the normal range.

Tetany may also be produced experimentally in animals by feeding them diets deficient in magnesium. In such instances the serum magnesium is lowered, but the calcium and phosphorus are within normal limits. Though a few isolated cases of tetany in the human subject have been attributed to magnesium deficiency, only one case has been reported in which the data are sufficiently impressive to suggest that this type of tetany may occur in man (Miller).

**Clinical Forms. Hypocalcemic tetany.** Serum calcium may be reduced by a number of factors, but, whatever the cause, when the total concentration falls below 7 or 7.5 mg. per 100 ml., symptoms of tetany are likely to occur. In *tetany of the newborn* (p. 342) it is postulated that there is temporary hypofunction of the parathyroid glands and that the serum calcium may be further lowered by too heavy initial feeding of cow's milk with its relatively high phosphorus content. After the first four weeks of life vitamin D deficiency (p. 378) and celiac disease (p. 723) are the most frequent causes of hypocalcemic tetany. Infrequently in children, hypoparathyroidism (p. 1175) is a factor.

**Tetany of alkalosis.** The mechanism of the tetany of alkalosis is not entirely understood; it is not associated with changes in the serum levels of calcium and phosphorus. It has been suggested that the shift of the acid-base balance of the blood to the alkaline side reduces the amount of ionized calcium without reducing the total serum calcium concentration. Though this concept is not completely substantiated, the fact that the symptoms of tetany can be abolished by acid salts or other factors which decrease the pH of the

blood without altering the level of the serum calcium or phosphorus can be accepted as evidence in favor of it. Clinically, the tetany of alkalosis may be observed in conditions responsible for excessive overbreathing (hyperventilation tetany), loss of chloride (gastric tetany) or excessive intake of bicarbonate (bicarbonate tetany).

In *hyperventilation tetany* there is an excessive loss of plasma carbonic acid with a lesser loss of bicarbonate. The pH of the blood is elevated, but the carbon dioxide content is decreased (respiratory alkalosis, p. 179). Overbreathing may be due to hysteria or high altitude or to irritation of the central nervous system by infectious or toxic agents.

Table 108. Differential Data of Various Types of Tetany\*

Type of Tetany	Usual Age Distribution	Serum Calcium	Serum Phosphorus	Bicarbonate of Blood	pH of Blood	Serum Phosphatase	Excretion during Low Calcium Diet			
							Urine		Feces	
							Ca	P	Ca	P
Tetany of the newborn	First 2-3 weeks of life	Low	High			Normal				
Hypocalcemic Tetany										
Vitamin D deficiency—rickets (infantile tetany)	3 months -3 years	Low	Low or normal	Normal	Normal	High	Low	Low	Low	Low
Celiac disease	Infancy and childhood	Low	Low or normal	Normal	Normal	Normal or slight increase	Low	High	High	Normal
Hypoparathyroidism: traumatic; idiopathic surgical	Children and young adults Young adults	Low	High	Normal	Normal	Normal	Low	Low	Normal	Normal
Pseudohypoparathyroidism (Albright)	Any	Low	High							
Tetany of Alkalosis										
Hyperventilation	Any	Normal	Normal	Low	High					
Gastric (vomiting)	Any	Normal	Normal	High	High					
Bicarbonate	Any	Normal	Normal	High	High					
Other and Experimental Types of Tetany										
Phosphate		Low	High	Normal	Normal or high					
Magnesium deficiency		Normal	Low or normal							
Guanidine		Normal or slightly lower	Normal or slight increase							

\* Adapted from Aub; Best and Taylor; and Shelling.

FIG. 328. Carpal spasm in tetany.

*Gastric tetany* follows loss of chloride ions from excessive vomiting, repeated gastric lavage or gastric retention. It is occasionally observed in pyloric stenosis and in high intestinal obstruction. The chloride of the serum is reduced and the bicarbonate elevated. The carbon dioxide content and the pH of the blood are increased.

*Bicarbonate tetany* occasionally results from ingestion or intravenous administration of sodium bicarbonate. Both the carbon dioxide content and the pH of the blood are elevated. The danger of administration of bicarbonate in the presence of vomiting or renal insufficiency cannot be overemphasized.

**Clinical Manifestations.** The symptoms of tetany are essentially the same, irrespective of the etiology, and reflect a state of increased neuromuscular irritability. There are, of course, clinical manifestations peculiar to each of the various disturbances with which tetany is associated. The manifestations of tetany may be divided into two phases, latent and manifest.

**Latent tetany.** In the latent phase there are no spontaneous manifestations, but increased neuromuscular excitability may be elicited by the mechanical or electrical means described below. The diagnosis is confirmed in hypocalcemic tetany by a low serum calcium level.

**CHVOSTEK'S SIGN.** This is a unilateral

contraction of the facial muscles about the mouth, nose and eye when the area in front of the auditory meatus, where the facial nerve approaches the surface, is tapped. It cannot be obtained while the infant is crying. A positive Chvostek's sign is normal in the newborn infant and is obtained frequently in healthy children over five years of age, but in the age range of vitamin D-deficient tetany, three months to three years, it is strong presumptive evidence in favor of tetany.

**PERONEAL SIGN.** This is elicited by tapping the peroneal nerve just below the head of the fibula while the knee is relaxed and slightly flexed. A positive response consists in dorsal flexion and abduction of the foot.

**TROUSSEAU'S SIGN.** This is based on the production of carpal spasm. It is elicited by maintaining firm constriction of the upper arm for two or three minutes after the hand has become blanched. When the test is positive, the hand assumes the position of carpal spasm, which is described below under Carpopedal Spasm.

**ERB'S SIGN.** This is obtained by measuring the amount of galvanic current required to elicit a muscular contraction and is based on the greater muscular irritability of the patient with tetany. It is the most sensitive of the various tests, but requires skill for its performance and interpretation. The current required to obtain anodal and cathodal contractions is measured on a milliammeter. The electrodes are moistened in saline solution; the indifferent one is placed on the abdomen, and the stimulating one over the nerve to be tested. The peroneal nerve is usually used. The average electrical thresholds for the various ages are shown in Table 109. More current is required to elicit a response in an infant than in an older child. The response to the cathodal opening contraction (C.O.C.) is considered to be most significant; when this is obtained in children under five years of age with less than 5 milliamperes of current, it is pathognomonic of tetany. An anodal opening contraction (A.O.C.) obtained with less current than the anodal closing contrac-

Table 109. Typical Electrical Thresholds (in Milliampères) in Normal Persons at Different Ages\*

Age	C.C.C.	A.C.C.	C.O.C.	A.O.C.	
Under 6 months.....	3.5	7.0	10.0	9.0	A.O.C. > A.C.C.
About 1 year.....	2.5	5.0	8.0	6.0	A.O.C. > A.C.C.
Over 5 years.....	1.8	4.0	6.5	3.5	A.O.C. < A.C.C.

FIG. 329. Pedal spasm.

tion (A.C.C.) and with less than 5 milliamperes of current during the first six months of life or with less than 2 milliamperes from the age of four to five years is also considered characteristic of tetany.

**Manifest tetany.** This phase is characterized by spontaneous muscular twitchings and spasms, laryngospasm and convulsions.

**CARPOPEDAL SPASM.** This is perhaps the most characteristic feature of tetany. The thumb is drawn into the cupped palm, the hands are abducted and the wrists flexed, and the fingers are flexed at the metacarpophalangeal joints, but extended at the more distal ones (Fig. 328). The foot is extended in the position of talipes equinus or equinovarus, the toes flexed, and the sole cupped (Fig. 329). Both the arms and the legs may be rigidly flexed and adducted.

**LARYNGOSPASM.** This is a relatively common manifestation and may be characterized simply by an inspiratory, high-pitched crowing sound, but in extremely severe cases there is such spasm that respirations may cease for an uncomfortable interval and the infant become quite cyanotic. Rarely intubation is required for relief, and occasionally an infant has died during such an attack.

**CONVULSIONS.** These do not differ from other generalized seizures, except as there may be carpopedal spasm.

**Diagnosis.** The diagnosis is based on the clinical manifestations and the laboratory data. Of the latter, the important measurements are the serum calcium in hypocalcemic

tetany and the pH of the blood in the tetany of alkalosis. These and other data are detailed in Table 108.

In the differential diagnosis other causes of convulsions must be considered (p. 1115), as must other conditions which may be responsible for laryngospasm or stridor. *Congenital stridor* is eliminated as a possibility, since it is present from birth. The laryngospasm of *pertussis* has been confused with that of tetany. The characteristic cough of *pertussis*, with absence of other signs of tetany, should establish the diagnosis, which, in many instances, may be confirmed bacteriologically. *Acute laryngeal infections* are characterized by fever and other evidences of infection. Breath-holding spells may be confused with tetany, but a history of previous episodes, the relation to fits of temper and the absence of other signs of tetany are differential factors.

**Treatment.** Treatment of the various hypocalcemic tetanies is considered under their respective headings. In tetany due to alkalosis primary attention should be directed to relieving the cause. In hyperventilation tetany, rebreathing into a paper bag and inhalation of carbon dioxide are helpful procedures. Carefully controlled sedation is usually indicated to decrease the hyperpnea. In gastric tetany the underlying disturbance should be controlled, if possible, and generous amounts of physiologic saline solution should be administered parenterally. Acid salts such as ammonium chloride or calcium lactate may be administered orally if vomiting is controlled.

# Convulsive Disorders

Convulsive phenomena are common symptoms in children and occur with a wide variety of disorders of the central nervous system. Seizures may be classified according to (1) their etiology or pathogenesis (see Table 110), (2) their clinical manifestations, and (3) their electroencephalographic pattern.

**Incidence at Various Ages.** In clinical practice consideration of the relative incidence of the various etiologic factors at different ages (Fig. 330) is frequently helpful in arriving at a correct diagnosis and in evaluating prognosis.

Convulsions are far more common during the first two years than at any other period of life. Intracranial birth injuries, including the effects of anoxia and hemorrhage and congenital defects of the brain, are the most

frequent causes of convulsions in very young infants. In the latter part of infancy and in early childhood acute infections (extracranial and intracranial) are the most frequent causes. Far less frequent causes in infants are tetany, idiopathic epilepsy, spontaneous hypoglycemia, brain tumors, renal insufficiency, poisoning, asphyxia, spontaneous intracranial hemorrhage and thrombosis, postnatal trauma and others listed in Table 110. By midchildhood acute extracranial infections have become an infrequent cause of convulsions, whereas idiopathic epilepsy, first appearing as an important cause of convulsions about the third year of life, is the most common etiologic factor.

Other causes of convulsive seizures in the postinfancy period are congenital defects of the brain, residual cerebral damage from

FIG. 330. Comparative incidence of different causes of convulsions at different ages from birth to the sixteenth year of life. The data used in the construction of this chart are representative of pediatric experience in children's clinics in the northern part of the United States, covering the period between 1925 and 1940. It is likely that there are some variations in the percentage distribution of causes of convulsions at various ages at present. In particular there is probably a significant decrease in those due to tetany of vitamin D deficiency.

earlier trauma, infection, lead poisoning, phritis and certain degenerative diseases of brain tumors, acute or chronic glomerulone- the brain.

<i>I. Acute or Nonrecurrent Forms</i>	
"Febrile convulsions" (e.g., at onset of acute extracranial infections; in association with high environmental temperatures)	
Intracranial infections (e.g., acute meningitis, encephalitis, sinus thrombophlebitis, cerebral abscess, tetanus, malaria, typhus fever)	
Intracranial hemorrhage (e.g., from birth or other trauma, hemorrhagic disease, rupture of defective vessels)	
Toxic:	
1. Convulsant drugs (e.g., camphor, thujone, Metrazol, strychnine)	
2. Kernicterus	
3. Lead encephalopathy	
Anoxic (e.g., sudden severe asphyxia, inhalation anesthesia)	
Metabolic or nutritional (e.g., acute hypocalcemic tetany, alkalosis, therapeutic hypoglycemia, pyridoxine deficiency)	
Acute cerebral edema (e.g., in acute glomerular nephritis or allergic edema of the brain)	
Brain tumor	
Miscellaneous	
<i>II. Chronic or Recurrent Forms</i>	
Epilepsy:	
1. Idiopathic (primary, cryptogenic, essential or genuine epilepsy)	
(a) Hereditary or genetic type	
(b) Nongenetic or acquired idiopathic type (?)	
2. Organic (secondary or symptomatic epilepsy—with residual brain damage from previous focal or diffuse injuries)	
(a) Post-traumatic (e.g., from direct laceration of brain tissue)	
(b) Posthemorrhagic (e.g., from injury at birth or later, from hemorrhagic diseases, pachymeningitis, rupture of miliary aneurysm)	
(c) Postanoxic (e.g., from severe asphyxia neonatorum)	
(d) Postinfectious (e.g., following encephalitis, meningitis, sinus thrombophlebitis or abscess)	
(e) Post-toxic (e.g., kernicterus, encephalopathy following lead, arsenic or other chronic poisoning)	
(f) Degenerative (e.g., "idiopathic atrophy," cerebromacular degeneration, encephalitis periaxialis diffusa, intracranial neurofibromatosis)	
(g) Congenital (e.g., cerebral aplasia, porencephaly, tuberous sclerosis, hydrocephalus, vascular anomalies such as the Sturge-Weber type and arteriovenous aneurysms)	
(h) Parasitic brain disease (cysticercosis, toxoplasmosis, syphilis)	
(j) Posthypoglycemic injury	
Epilepsy-simulating states:	
Narcolepsy and cataplexy	
Hysteria ("psychogenic epilepsy")	
Tetany	
1. Hypocalcemic (e.g., idiopathic, postoperative, neonatal, vitamin D deficiency, deficient intestinal absorption)	
2. Of alkalosis (e.g., vomiting, administration of bicarbonate, hyperventilation)	
Hypoglycemic states	
1. Hyperinsulinism (e.g., tumor or hyperplasia of islets of Langerhans)	
2. Hypopituitarism (e.g., deficiency of adrenocorticotrophic, thyrotropic and growth hormones)	
3. Adrenal cortical insufficiency	
4. Hypothyroidism (e.g., cretinism)	
5. Hepatic disorders (e.g., von Gierke's disease)	
6. Miscellaneous (e.g., familial type, idiopathic)	
Uremia	
"Cerebral" allergy	
Cardiovascular dysfunction or syncopal attacks (e.g., simple fainting attacks, Stokes-Adams syndrome, hyperactive carotid sinus reflex)	
Migraine	

## ACUTE OR NONRECURRENT CONVULSIVE DISORDERS

The causes of acute convulsive attacks in children are extremely varied (Table 110). Any type of seizure may occur as a transient manifestation of acute disease involving the brain, but generalized tonic and clonic convulsions similar to the grand mal attack of epilepsy are by far the most common. Practically all seizures resulting from extracranial disorders are of this type.

Approximately 6 to 8 per cent of all children have "febrile convulsions," most of which occur after the first six months of life, but within the first two to three years. The incidence decreases progressively up to six to eight years of age, after which such seizures are exceedingly rare. Males are more often affected than females, and there appears to be an increased susceptibility in some families.

**Diagnosis.** Though most of the convulsions which occur in the latter part of infancy and in the first few years of childhood merely represent an initial symptom of an acute febrile illness, each child who has had a convulsion should be examined for the possibility of some other cause. Such disorders as tetany, lead encephalopathy, intracranial injury, hemorrhage or tumor, poisoning with a convulsant drug, hypoglycemia, asphyxia, cerebral sinus thrombosis (associated with cyanotic congenital heart disease and cachexia), acute nephritis and epilepsy should be considered. Figure 330 indicates the importance of considering the age factor as an aid to diagnosis.

A carefully taken history of previous attacks, of immediately preceding symptoms such as hyperirritability, fever, muscular cramps, headache, vomiting or dizziness, of a possible dietary deficiency, of poisoning of any kind, of cranial injury, of a hemorrhagic tendency, of exposure to infection or of a hereditary predisposition to seizures is invaluable for orientation.

A complete physical examination, including a thorough neurologic appraisal, is essential. Inspection of the eyegrounds may give the first clue to the nature of the primary illness by revealing an optic neuritis or choking of the disks. These may occur in the presence of an expanding intracranial lesion (tumor, cyst, hemorrhage or abscess), acute hydrocephalus or severe encephalitis. Such examination may also reveal the presence of

retinal hemorrhages, suggesting intracranial bleeding from trauma or a blood dyscrasia. Albuminuric retinitis may furnish the first clue to the presence of subacute or chronic nephritis. There may be slight choking of the optic disks in acute nephritis with arterial hypertension. The chorioretinitis of toxoplasmosis, the reddish areas of degeneration in the macular region in cerebromacular degenerative disease, and the choroidal tubercles of miliary tuberculosis are highly characteristic.

Determinations of the calcium and inorganic phosphorus of the serum, of the sugar and urea nitrogen of the whole blood will aid in the diagnosis of hypocalcemic tetany, hypoglycemia and acute nephritis, respectively. Coexisting hypertension, albuminuria and cylindruria are evidences of nephritis. Roentgenographic examinations may show the "lead line" of lead poisoning in the long bones, or thinning of the skull and separation of the sutures in the presence of an expanding intracranial lesion.

If the primary disease is infectious, it should be ascertained whether the infection is extracranial ("febrile" or "prefebrile" convulsions) or intracranial. It is necessary to determine whether an intracranial infection is meningitis, encephalitis, abscess, sinus thrombophlebitis or tetanus. Certain other infectious diseases, such as typhus fever and malaria, which produce local lesions in the brain may occasionally cause convulsions; in some instances the convulsions are related to disturbances of water and electrolyte balance.

**Treatment.** For the control of "febrile" convulsions which occasionally occur at the onset of acute extracranial infections a sedative dose of phenobarbital (3 mg. per kilogram of body weight) and reduction of the elevated body temperature usually suffice.

If the convulsion is prolonged or if the child has a second convulsion before he recovers fully from the first, more vigorous anticonvulsant treatment is indicated (see p. 1117). The appropriate treatment for other conditions which may be responsible for acute convulsive seizures is detailed elsewhere.

Seizures secondary to electrolyte disturbances require special therapy (see p. 192). After other causes for seizures have been excluded as well as it is possible to do so a

clinical trial of pyridoxine may be indicated in young infants (see p. 110).

**Prognosis.** When a seizure is a result of some physical or metabolic disturbance, the prevention of recurrent convulsions is dependent upon the eradication or control of the underlying disease.

After a single "febrile" seizure the family can be reassured that the probability of chronic epilepsy is not great. The occurrence of more than one "febrile" seizure increases the probability of subsequent spontaneous nonfebrile convulsions. According to Livingston, there is a relatively high probability that idiopathic epilepsy will develop in children who have more than five "febrile" convulsions in a twelve-month period, single seizures which last for more than one hour, or persistent electroencephalographic abnormalities. However, the electroencephalogram of a child who has had a febrile convulsion may be abnormal as long as a week afterward. Approximately 25 per cent of epileptic children do not have a history of "febrile" seizures.

Present evidence seems to indicate that daily anticonvulsant therapy does not reduce the number or duration of "febrile" convulsions. Therefore, as long as the physician feels that a child has "febrile" convulsions, such therapy is not indicated. When convulsions recur with little or no evidence of infection or if the electroencephalogram is significantly abnormal two weeks or more after the last seizure, a therapeutic trial of daily anticonvulsant therapy may be indicated.

An infant or young child who has had one or more "febrile" seizures is entitled to more prompt antipyretic measures, such as aspirin or tepid sponges, and *anti-infectious* therapy than might otherwise seem indicated. Some physicians give phenobarbital prophylactically to such infants during a febrile episode. If anti-infectious or anticonvulsant therapy is prescribed, the physician must observe the child closely for the possibility that such serious infections as meningitis may be masked.

## CHRONIC OR RECURRENT CONVULSIONS

### EPILEPSY

The terms *epilepsy* (from the Greek *epilēpsia*, a seizure) and *recurrent convulsive disorder* can be used interchangeably. These terms designate a variable symptom complex characterized by recurrent, paroxysmal attacks of unconsciousness or impaired consciousness, usually with a succession of tonic or clonic muscular spasms or other abnormal behavior. If a cause of the patient's seizures cannot be found, he may be said to have *idiopathic* or *cryptogenic epilepsy*; if a cerebral abnormality is demonstrable, *organic* or *symptomatic* epilepsy.

Because many persons, from prejudice or ignorance, feel that a person with epilepsy will somehow fail to make an adequate social adjustment, some physicians are reluctant to use the term "epilepsy" in discussing the problem with parents. Although its use without a previous explanation of its meaning may be potentially harmful, an affected family should know the term and how it applies to them. This is part of the physician's responsibility as he educates the family toward living more comfortably with a chronic ill-

ness. There is considerable variation in a family's ability and desire to acquire information about a chronic illness. Too much information on a single visit is undesirable (see p. 1122). Orientation should be a continuing process, especially during the early period of medical supervision.

**Idiopathic Epilepsy.** Approximately 60 per cent of children who have a recurrent convulsive disorder before fourteen years of age have idiopathic epilepsy. The onset is between the ages of four and eight years in about 50 per cent; less than 2 per cent of them have a convulsion before the age of two years (Fig. 330). In most instances there is no significant degree of mental retardation and no significant physical defect. Acceptable prophylactic control of the seizures is possible in at least 85 per cent of such patients.

The underlying cause of the convulsions has not been determined. It is possible that a specific genetic defect in cerebral metabolism is responsible in most instances.

Electroencephalographic tracings, particularly during sleep, show definite generalized abnormalities in 90 per cent of children with

idiopathic seizures. Rarely there are focal electroencephalographic abnormalities; on repeated examinations a focus often migrates from one area to another. Lennox has pointed out that electroencephalographic abnormalities (cerebral dysrhythmias) are more likely to be found in parents and siblings of affected children than in the population at large. However, a hereditary factor is usually not clinically demonstrable.

**Organic Epilepsy.** A variety of genetically determined conditions (Table 110) are associated with seizures. These disorders have abnormalities demonstrable anatomically (congenital ectodermoses) or biochemically (phenylketonuria). In addition, convulsions may occur after cerebral damage acquired in the prenatal, natal or postnatal period. Neurologic examination of such children frequently shows a motor handicap of central nervous system origin (cerebral palsy) and mental retardation. These patients almost always have electroencephalographic abnormalities.

The recognition of genetically determined conditions is important for several reasons: (1) Cerebral damage in younger siblings of affected patients may be prevented in certain instances by prompt and effective therapy (congenital hypoglycemia, phenylketonuria, kernicterus). (2) Less characteristic signs and symptoms in siblings may be more readily recognized (tuberous sclerosis, lipochondrodystrophy, neurofibromatosis). (3) Identification of an organic etiology of the seizures is important prognostically; in general, control of such seizures is less good and social adjustment of the child less adequate than in children with the idiopathic form.

**Clinical Manifestations.** *Grand mal seizures.* These seizures may be preceded by a momentary aura, but fewer than a third of epileptic children can give a definite description of such an experience. In some cases a preliminary, localized spasm or twitching of muscles may precede a generalized seizure. This is often referred to as a "motor aura," or warning. Vague prodromal symptoms or signs, such as irritability, digestive disturbances, headache and mental dullness, may forewarn patients or their parents of impending motor seizures. The period intervening is usually short, but may be hours or even a day or two.

Grand mal seizures are generalized convulsions, usually with tonic and clonic phases of the muscular spasms. The onset of the paroxysm is abrupt, and the tonic spasm may occur simultaneously with loss of conscious-

ness. The patient, if sitting or standing, falls to the ground. His face suddenly becomes pale, the pupils dilate, the conjunctivas become insensitive to touch, the eyeballs roll upward or to one side, the face is distorted, the glottis is closed, the head may be thrown backward or be twisted forcibly to one side, the abdominal and chest muscles are held rigidly, and the limbs are contracted irregularly or stiffen out. As the air is forced out of the lungs through the glottis by sudden contraction of the diaphragm and the intercostal muscles, a short, startling cry may be heard. The tongue may be severely bitten as a result of the rapid contraction of the jaw muscles. Micturition and less frequently defecation may follow the sudden forceful contraction of the abdominal muscles. As the tonic phase of the seizure continues, facial pallor is quickly followed by suffusion and this in turn by cyanosis, occasionally severe, due to arrest of all respiratory movements. At the end of this phase, which usually lasts not more than twenty to forty seconds, the clonic phase sets in, and lasts for variable periods of time.

The patient may awake from his postconvulsive sleep with a severe, generalized headache and in a state of confusion. He may go about in a semidazed or stuporous state in which he may perform more or less automatic acts without being able to recollect what he has experienced. These postparoxysmal or postictal reactions are interpreted as malfunctioning of neurons which have not yet recovered from the effects of the seizure. These may be so severe as to result in prolonged automatism, transient paresis or, more rarely, in hemiplegia or other paralytic manifestations of focal injury or hemorrhage.

A grand mal seizure may occur at night (nocturnal epilepsy) without the patient's being aware of it. A bitten tongue or lip, headache, blood on his pillow or a bed wet with urine may be the only clue. Generalized motor seizures tend to be predominantly tonic during infancy, although the clonic feature is always present to some degree.

So-called secondary symptomatology, which pertains chiefly to personality traits such as egocentricity, shallowness, religiosity and chronic negativism and which is considered by some to be characteristic of epilepsy, is much less prominent in children than in adult patients. When such personality traits are manifest, they usually represent the patient's response, over a long time, to psychogenically injurious attitudes of other people toward him and his disability. These traits are not

to be attributed to the disease per se or confused with the transient behavior disturbances of psychomotor attacks. Similar personality disturbances develop frequently for the same general reasons in victims of any chronic handicapping condition.

**Petit mal seizures.** These seizures consist in a transient loss of consciousness. There may be such minor manifestations as an upward rolling of the eyes, moving of the lips, drooping or rhythmic nodding of the head, or slight quivering of the trunk and limb muscles. Clinical evidence of petit mal rarely appears before three years of age, and frequently disappears by the time of puberty. Girls are more often affected than boys. Intellectual development is rarely impaired in children who have only simple, staring petit mal seizures. Attacks of this type last less than thirty seconds and are most frequently described by parents or other associates of the child as "dizzy spells," "absences," "lapses" or "fainting turns." The patient rarely falls, but usually drops articles which he may have in his hand or mouth at the time. If performing an act such as writing or reading at the time of onset, he will suddenly discontinue it, and then resume it when the seizure is ended. He may not be aware of having had a convulsion. Such seizures vary in frequency from one or two a month to as many as several hundred a day. Individual petit mal seizures may, in rare instances, become progressively prolonged and gradually resemble a mild form of grand mal. Prolonged episodes of confusion, inappropriate action and loss of ability to speak or understand (petit mal status) are rare and can be distinguished from psychomotor seizures only by an electroencephalogram during the attack.

**Pyknolepsy.** Pyknolepsy (pyknoepilepsy, "myriad spells") is the designation used by Adie to describe a clinical state in which mild petit mal seizures suddenly appear in great numbers in otherwise normal children between the ages of three and ten years. Such episodes recur over a period of months or years, then cease spontaneously and permanently without impairment of the victim's mentality. The electroencephalograms of such patients are typical of petit mal epilepsy. There appears to be little justification for setting this condition apart as a separate clinical entity.

**Psychomotor seizures.** Psychomotor seizures are the most difficult to recognize and, except for infantile myoclonic spasms, to control. They consist in purposeful but inap-

propriate motor acts, which are repetitive and often complicated. Most frequently a slight aura may manifest itself in a young child by a shrill cry or an attempt to run for help. Often the child is drowsy or sleeps for a short time after the spell. The seizure itself often consists in a gradual loss of postural tone. For example, the child may extend one arm and make a slow half-turn to one side while falling slowly to the ground. He often has vasomotor changes, such as circumoral pallor. After a one- to five-minute episode of unconsciousness the child may resume his normal activity or may sleep. There are usually no tonic or clonic movements. Fugue states or episodes of confusion, which may resemble petit mal status, are rarely noted in children. A normal electroencephalogram, except at the time of a psychomotor seizure, is not uncommon. Treatment is similar to that of grand mal seizures.

**Focal seizures.** These seizures may be sensory or motor in type (jacksonian epilepsy), depending upon the location of the focal area of abnormal neuronal discharge. Localized sensory attacks which give rise to a variety of symptoms are rare in children. Focal seizures, either sensory or motor, may occasionally occur in the absence of organic lesions. Although they are not infrequently preceded by a brief tonic phase, unilateral motor or jacksonian attacks are typically clonic, indicating their origin in the motor cortex. The muscles most frequently involved in a jacksonian seizure are those most specialized for voluntary purposes—most frequently those of the hand, face or tongue and less often of the foot and trunk.

As might be expected from the relationship of the areas of representation of the various muscle groups in the precentral gyrus, a focal motor seizure beginning in one member spreads or extends to others according to a fixed pattern, e.g., from thumb to fingers, to wrists, to arm, to face and then to the leg on the same side ("jacksonian march" of muscle spasms). When such an attack is of brief duration and remains localized to one area, consciousness may not be disturbed. When its spread is extensive and rapid, however, consciousness is lost, and a generalized convulsion follows, indistinguishable from a typical grand mal seizure.

**Infantile myoclonic seizures.** This term describes a type of convulsive seizure in infants which is also variously termed "infantile spasm," "lightening major" and "jack-knife epilepsy." Unlike true petit mal seizures,

these episodes occur before two years of age and involve more than a single group of muscles. The most common type of mass myoclonus consists in a sudden dropping of the head and flexion of the arms. The attack may be repeated several hundred times a day. The electroencephalographic changes suggest a diffuse, disorganized state and consist of random high voltage slow waves and spikes (hypsarrhythmia). It is one of the most characteristic encephalographic patterns. An underlying defect in cerebral metabolism appears to be responsible. Although the convulsive manifestation tends to disappear after the second or third year of life, most children with this condition are seriously retarded mentally and may later have grand mal seizures.

Unless a specific cause such as phenylketonuria can be discovered, control of the seizures has been generally unsatisfactory. For infants who developed normally before the onset of seizures, Sorel has suggested therapy with corticotropin. His plan of therapy consists of 5 units of ACTH gel daily in conjunction with Thorazine (5 mg. three times a day) and Mysoline (125 mg. twice a day) for fifteen days. If electroencephalographic abnormalities were present eight days later, the course of therapy was repeated. Infants who had had seizures for less than two months prior to therapy were said to have recovered completely; those with illness of longer duration continued to be mentally retarded. This form of therapy requires further evaluation.

**Myoclonic and akinetic seizures.** Occasionally children with or without other clinical manifestations of epilepsy have myoclonic jerks or involuntary muscular contractions with or without loss of consciousness. A single group of muscles is usually affected. A patient may have a normal electroencephalogram while he is having myoclonic jerks involving one side or one extremity. The origin of the seizure is presumed to be subcortical in such instances.

An akinetic seizure is associated with a sudden generalized loss of postural tone and therefore differs from single or repeated myoclonic jerks. These seizures in young children may resemble infantile myoclonic seizures and are sometimes called motor petit mal, jackknife or akinetic seizures. The electroencephalogram usually reveals spike and wave pattern of less than 3 per second.

Minor motor seizures are often associated with a degenerative disease, mental retarda-

tion or other central nervous system disorders and may be difficult to control.

**Diagnosis. Electroencephalography.** In practically all instances an electroencephalogram should be obtained when there is clinical evidence of a convulsive disorder. An exception may be made in a child with an obvious clinical diagnosis of the staring type of petit mal seizure, since the characteristic three per second spike and wave pattern is almost invariably present.

Three types of rhythms have been described in the electroencephalogram of the normal human adult. The most common one, the alpha rhythm, consists of regular sinusoidal waves occurring at frequencies of eight to twelve per second, with a voltage of 20 to 60 microvolts when recorded from the scalp. The second most common, or the beta rhythm, is most prominent in the frontal cortex. It has a lower amplitude, and a frequency of thirteen to thirty-two per second. The least common, or gamma rhythm, arises from the frontal lobes and consists of a more rapid, thirty-three to fifty-five, rate per second with waves of extremely low voltage. Slower waves (theta, five to seven per second, and delta, one to four per second) are not present in normal adults during the waking state.

The interpretation of the electroencephalogram of infants and children is more difficult than that of adults because of the presence of slow rhythms (three to eight per second) in normal children. Cortical rhythm is poorly developed in the newborn. As the infant matures, the electroencephalogram shows random three to seven per second waves and some low voltage faster activity. Gradually the basic rhythm becomes more regular, and by six years of age the pattern is made up principally of five to seven per second waves, and by ten years alpha waves, eight to twelve per second, predominate. During adolescence some slow wave activity, four to eight per second, is not uncommon and may be incorrectly interpreted if adult standards are used.

Sleep, without the use of a hypnotic, hyperventilation for two minutes, Metrazol, artificially induced fever, the Pitressin test and a flickering light serve to bring out latent abnormalities in the electroencephalogram and may on occasion produce a seizure. Of these, sleep and hyperventilation are most frequently used in cooperative subjects.

**ABNORMAL WAVES.** Most patients with frequent grand mal seizures have definite

abnormalities in their electroencephalograms in the intervals between seizures. These consist of random spike discharges, diffuse high voltage slow waves or a pattern not consistent with the child's chronologic age. An electroencephalogram obtained during a grand mal seizure shows multiple high voltage spike discharges. After the seizure there are asymmetries between the two hemispheres and diffuse slowing.

Patients with seizures other than grand mal have a variety of electroencephalographic abnormalities. The most easily recognized one is that of infantile myoclonic seizures with its high voltage, one to two per second, spike and wave pattern, the so-called hypsarrhythmia (hyps=mountainous). The record gives the impression of complete disorganization.

During petit mal attacks there is a three per second spike and wave pattern with a well developed basic rhythm interrupted by spike and wave activity.

Spike discharges, particularly in the temporal area, are usually associated with clinical abnormalities. In the anterior temporal areas, older children with psychomotor seizures may show intermittent bursts of six to fourteen per second spikes. A constant asymmetry of one area compared to its counterpart on the opposite side may be significant, especially if the electrical activity shows phase reversal of slow waves. Shifting foci are more common in children than in adults and indicate a functional disturbance rather than an anatomic lesion. Absence of electrical activity over an area suggests a large lesion such as a subdural collection of fluid or an abscess. Serial electroencephalograms of children with hydrocephalus show a disturbance of function as the process progresses. After cerebral insults such as trauma, encephalitis, cerebral thrombosis and prolonged seizures, electrical activity may be slow for a variable time and may be roughly correlated to the child's clinical course.

Metabolic disorders, such as hypoglycemia, hyperthyroidism and adrenal insufficiency, alter cortical activity; the clinical significance of these changes is not clear.

Various types of cerebral dysrhythmia may occur for short times between clinical seizures. The occurrence of abnormal discharges of short duration, such as a single wave and spike formation or a short series of spikes similar to those in grand mal seizures, without clinical manifestations has given rise to the designation of subclinical or larval sei-

zures. These subclinical bursts may at times foretell the onset of clinical seizures.

**Roentgenography.** A roentgen examination of the skull is considered an essential part of the diagnostic appraisal in search for such abnormalities as intracranial calcifications, erosion of the base or increased densities as causes of organically determined seizures. A hammered-silver pattern of the cranium is

FIG. 331. Electroencephalograms of infants and children. A, These tracings were obtained from comparable areas of the scalp and represent electrical activity in the motor cortex. The variations of rhythm with age during a quiet phase just prior to sleep. B, The effect of sleep, variations of patterns in normal children; compare with tracings in A and C. C, Abnormal waves.

present so commonly that by itself it is not considered abnormal. Routine pneumoencephalography in the epileptic child is not considered necessary, since space-filling lesions without localizing peripheral neurologic changes which justify surgical exploration are an uncommon cause of convulsions in children.

The decision concerning additional laboratory examinations other than the routine urinalysis, blood cell count and tuberculin test should be based on leads obtained from the medical history, the physical examination and the clinical course. Examination of the cerebrospinal fluid need not be routine, but it may provide additional information when lead poisoning, certain instances of mental deterioration and encephalitis are considered diagnostically.

When hypoglycemia (p. 1215), nephritis (p. 1038) and tetany (p. 1110) are considered possible causes of convulsions, appropriate diagnostic steps are obviously indicated.

**Treatment. Management of the individual seizure.** Practically all that can be done for a patient during an attack is to protect him from bodily injury. This necessitates constant supervision in severe cases, especially when warning auras are absent before the attack. At the beginning of a major seizure clothing about the neck should be loosened. The patient should then be turned on his side so that he does not aspirate his pooled secretions. He should be observed carefully for changes in color; administration of oxygen is indicated during prolonged convulsions. As injury to the mouth and tongue frequently happens at the onset of the convulsion, the time-honored custom of placing a stick or other object in the mouth of the convulsive patient is potentially harmful and does little to improve the patency of the airway.

**Status epilepticus.** If a series of grand mal convulsions occurs before the patient has fully recovered, the prolonged seizure is termed status epilepticus. The intervals between individual convulsions may be so short that the seizures are virtually continuous. During status the muscular contractions may appear to be one-sided or to shift from one group of muscles to another. This does not constitute a true focal (jacksonian) seizure. Drug treatment of status consists in prompt administration of phenobarbital sodium intramuscularly (average doses, 60 mg. at six months of age to 120 mg. at two to three years, or 5 to 6 mg. per kilogram of body weight); if the convulsion is not controlled within twenty

minutes, the initial dose should be repeated. If the convulsion has been only partially controlled by this time, one-half the initial dose should be given. Subsequent administrations may be necessary. The rhythmic contraction of a single group of muscles following a severe convulsion does not require additional therapy. Sedative therapy should be limited to a single agent.

The dangers of intravenously administered barbiturates and of inhalation anesthesia are similar to those of anesthetizing an excited child. Such procedures are rarely necessary and, when indicated, should be performed by an experienced anesthesiologist. Laryngeal spasm and even sudden death may occur if treatment is too vigorous.

Administration of oxygen is indicated during prolonged convulsions, and administration of small amounts of 5 per cent glucose in 0.45 per cent saline solution intravenously may shorten the recovery time.

A quiet and otherwise calm atmosphere and reassurance and avoidance of unnecessary annoyance to the patient are important factors in general management, especially during the recovery phase.

**Continuous therapy of the epileptic child.** The aims of treatment are to reduce the number of seizures, to promote the acceptance of the child at home and in the community on the basis of his capabilities, and to encourage his functioning at a level commensurate with his natural endowment. For example, five grand mal seizures in the course of a year may be considered acceptable control in many instances.

The important therapeutic considerations include physical, emotional and mental hygiene, psychotherapy, anticonvulsant drugs and, rarely, a dietary regimen. The degree of success that can be anticipated depends upon a number of limiting conditions, such as the duration and severity of symptoms, the kind of seizures, the presence of a genetic factor, the presence of complicating cerebral lesions, and the capacity of the patient and his family to cooperate. Causative factors should be eradicated or alleviated whenever possible.

Initially the physician must secure the confidence and understanding of the child and his family. In the first few visits they should become aware of the nature of the disturbance, of what can be done to bring it under control and of what constitutes control. They need to know that the seizures of idiopathic epilepsy are not in themselves catastrophic and need not interfere with nor-

mal growth and development. The principal dangers are the attitudes of the child's family and his social contacts toward the disease. The child should attend school and participate in activities to which he is naturally inclined.

Parents, teachers, companions and especially the patient himself are usually only vaguely aware of the close relation between emotional or mental stresses and the occurrence of seizures. In older children a careful survey of the social relationships and a search for contributory emotional factors should be made from time to time with the hope of eliminating or avoiding mental conflicts and unnecessary anxiety. In hospital or clinic practice a social service worker can often render valuable assistance in ferreting out significant social factors which might otherwise be unknown. When the personality and the mental and emotional factors are complex, the co-operation of an experienced child psychiatrist is indicated.

Home and school surroundings which are not congenial and work requirements or responsibilities which are beyond the capacities or outside the interests of the patient may account for his failure to respond to therapy. Idleness and boredom have an especially deleterious effect on the epileptic child. In addition to a constructive program in school, he should be encouraged to occupy his spare time with interesting hobbies through which he can achieve favorable distinction. Self-confidence can thereby be sustained. The epileptic child is better off in his own home and in public school than in a special institution if his mental and emotional capacities permit it.

It is the duty of the physician, the nurse and the social worker who are acquainted with the problem to do everything possible to improve the attitude of the public toward the epileptic patient and his disease. Nearly every intelligent epileptic child sooner or later encounters attitudes toward him of pity and oversolicitousness or disgust and horror. These are likely to be a source of constant anxiety unless he is able to acquire an adequate philosophy.

**Drugs.** Since the introduction of bromides for the treatment of epilepsy by Leacock in 1858, drug therapy has been the choice and usually the only form of treatment. The tendency to rely upon medication alone was encouraged by the introduction of phenobarbital in 1912. Subsequently dietotherapy came into use when it was discovered that

fasting, the ketogenic diet and reduction of the water intake all tended to prevent epileptic seizures. Since the demonstration by Putnam and Merritt in 1937 that Dilantin (sodium diphenyl hydantoinate) was effective in the control of some patients not controlled by phenobarbital, the tendency to depend mainly upon drug therapy has again increased.

The successful management of the epileptic child requires determination of the most appropriate anticonvulsant drug or combination of drugs for him as well as the most appropriate dosages of them. To achieve this result, a systematic program for a trial of the various anticonvulsant drugs is necessary; a suggested schedule to determine an adequate therapeutic program is shown in Table 111. A change in the dose of a medication or from one medication to another should usually not be made more frequently than every two weeks.

*Phenobarbital* is the drug of choice for prolonged use in the average patient with grand mal epilepsy. Its virtues are its relative effectiveness, its comparative harmlessness in therapeutic doses for a prolonged time, its ease of administration and its low cost. Doses range from 8 mg. ( $\frac{1}{8}$  grain) one to three times daily for an infant to 100 mg. ( $1\frac{1}{2}$  grains) one to three times daily for an older child with a severe form of the disease. It may also be prescribed on a weight basis with an initial dose of 3 mg. per kilogram of body weight per day in two to four divided doses, with gradual increases to the required maintenance dose. More than 6 mg. per kilogram per day may result in drowsiness.

Occasionally a child will have an idiosyncrasy to phenobarbital. A maculopapular eruption on the skin and mucous membranes, excessive drowsiness and fever may be signs of sensitivity or overdosage. These soon disappear without permanent harm if the dose is reduced or if the drug is withdrawn. Rarely a patient, particularly one whose attacks are primarily petit mal, appears to be made worse by phenobarbital and has petit mal variants or psychomotor attacks. In such an event Dilantin may also be administered. Discontinuation of medication, which should always be done gradually, and substitution of another drug are rarely necessary.

**MEBARAL.** Mebaral (mephobarbital) is a barbiturate which is of value in some cases. The dose is approximately double that recommended for phenobarbital.

**DILANTIN.** The only drugs which rival the

Table 111. Schedule for Determination of Adequate Therapeutic Program in Epilepsy

Tridione					
(Not more than 900 mg. q.i.d.)					
20 mg./kg./day.....			3	6	
40 mg./kg./day.....			4	7	
60 mg./kg./day.....			5	8	

In this plan of therapy phenobarbital is given initially at the lower dose (1) and increased if necessary to the larger dose (2). It is prescribed and continued for all types of convulsions except as there are untoward reactions to it. If additional therapy is considered necessary, Dilantin is added. The dose is increased as deemed necessary as indicated above. Changes in medication or dosage are not made more frequently than two weeks. Mysoline is not used except as a supplement to Dilantin and phenobarbital. Mebaral may be used instead of phenobarbital, but at twice its calculated dose. The dose of Mysoline may also be calculated on the basis of body weight (15-25 mg. kg. day). Usually it is necessary to reduce the amount of phenobarbital by one third when Mysoline is added. The medications are given in divided doses 2-3 times each day.

barbiturates in the control of grand mal seizures are certain hydantoin compounds, such as diphenylhydantoin sodium, U.S.P., also known as phenytoin sodium (Dilantin). They are administered to older children in capsules and to younger ones in powder form mixed with a little food or fruit juice. Doses range from 15 mg. ( $\frac{1}{4}$  grain) two or three times daily in infants to 100 mg. ( $1\frac{1}{2}$  grains) one to four times daily in older children. The drug may also be prescribed on a weight basis with an initial dose of 3 mg. per kilogram of body weight per day in two to four divided doses, with gradual increases to the required maintenance dose. More than 8 mg. per kilogram per day may result in toxic manifestations. The chief advantage of hydantoin compounds over the barbiturates is that they act as efficient anticonvulsants without producing excessive drowsiness. One of these should be given a trial, therefore, whenever grand mal seizures are not adequately controlled by phenobarbital alone in nondepressing doses. Replacement should be made gradually, however, since sudden changes may result in increased convulsive reactivity.

The occurrence of nonpainful, nonhemorrhagic hypertrophy of the gums usually follows the administration of Dilantin. It usu-

ally requires no special treatment other than good dental hygiene. If it becomes unattractive cosmetically, another drug should be substituted.

Ataxia and drowsiness may occur if the initial dose is too large, if the dose is increased too rapidly or if the total daily dose exceeds about 8 mg. per kilogram per day. Serious toxic reactions such as nausea or vomiting, erythema or a morbilliform eruption, nervous manifestations such as tremor of the hands, ataxia, diplopia with nystagmus, paralytic manifestations and mild psychoses are uncommon. These disappear after reduction of the dose, usually to about two thirds of its former level.

TRIDIONE. Trimethadione or Tridione (3,5,5-trimethyloxazolidine 2,4-dione) is an effective drug for the treatment of petit mal epilepsy in doses of 0.3 gm. (5 grains) one to four times daily. The drug may also be prescribed on a weight basis with an initial dose of 25 mg. per kilogram per day in two to four divided doses, which may be gradually increased if necessary to 80 mg. per kilogram per day. Tridione may increase the occurrence of grand mal attacks if they also exist, and the additional administration of a barbiturate or hydantoin is indicated. Exces-

sive doses or prolonged use of Tridione may result in photophobia, hemeralopia, drowsiness, nausea, skin eruptions or nephrosis. Such manifestations tend to disappear promptly after withdrawal of the drug. Several fatalities from aplastic anemia and agranulocytosis have been reported in patients receiving Tridione regularly for several months. When it is given for more than a short time, periodic blood cell counts should be obtained, and the drug discontinued if any abnormality is found.

**PARADIONE.** Paradione is less toxic than Tridione, but also less effective. The dosage is similar to that of Tridione.

**MYSOLINE.** Mysoline or primidone (5-phenyl-5-ethyl-hexahydropyrimidine-4:6-dione) is used in the treatment of grand mal and psychomotor seizures. It may be used alone or in combination with other drugs and does not depress hemopoietic activity. The chief side effects, drowsiness, ataxia and dermatitis, can be minimized by starting with small amounts (125 mg.) at bedtime and by increasing the dose slowly at seven- to ten-day intervals to a maximum dose of 250 mg., three times daily.

**Special diet therapy.** Fasting causes cessation of grand mal seizures in a majority of epileptic children, the effect usually manifesting itself shortly after ketosis has appeared on the third day. A strongly *ketogenic diet* has a comparable anticonvulsive effect after ketosis has developed. Stringent restriction of the water intake, even when the diet is nonketogenic, results in cessation of grand mal seizures in most of those patients who respond favorably to fasting or the ketogenic diet. Establishment of a negative water balance, by restricting the intake or increasing the output, intensifies the anticonvulsive effects of the ketogenic regimen. Administration of alkaline salts in sufficient amounts to neutralize the acidogenic effect of fasting or of the ketogenic diet abolishes the anticonvulsive action, whereas administration of inorganic acids or acid-forming salts fortifies or intensifies such action. The ketogenic diet is beneficial for both petit mal and grand mal epilepsy.

The value of fasting is that it can be used to determine in a short time whether a patient with severe epilepsy is likely to respond favorably to a ketogenic diet. If the incidence and severity of seizures are not sharply reduced after three to five days of fasting and moderate restriction of the water intake, it is improbable that the patient will be benefited

by the ketogenic diet. If the diet is to be prescribed after a favorable fasting test, it is advantageous to start it immediately to ensure continuance of the ketosis.

It is necessary to supplement the diet with vitamin concentrates (p. 107), and at least 1 gm. of calcium should be included in the daily intake. Between 1.5 and 2 gm. of protein per kilogram of body weight per day should also be provided.

Dietary treatment is usually more successful if it is initiated for a week or two in a well regulated hospital. Intelligent older children and the parents can be taught the details of the dietary management and the technique of determining the presence of acetoacetic acid in the urine and the urinary specific gravity. Dietotherapy is most likely to succeed when the specific gravity of the urine is made to range above 1.020 and the urine turns a dark brown to deep burgundy red on addition of an excess of 10 per cent ferric chloride solution. It is essential that the various constituents of the diet be weighed carefully at first if success is to be expected. The diet should be made palatable and varied as much as possible.

Calculation of trial diets is facilitated by use of the following formulas:

1. *For Children of Preschool Age (or Body Weight up to 19 Kg.):*

Total	
water	.. 30 to 50 cc. per kg. of body weight
Protein	.. 2 gm. per kg. of body weight
Carbohy-	
drate	.. 0.7 gm. per kg. of body weight
Fat (gm.)=	$\frac{60 \times \text{kg. of body weight}}{9}$

2. *For Children between the Ages of 6 and 10 Years (or 20 to 32 Kg. Body Weight):*

Total	
water	.. 25 to 40 cc. per kg. of body weight
Protein	.. 1.5 gm. per kg. of body weight
Carbohy-	
drate	.. 0.5 gm. per kg. of body weight
Fat (gm.)=	$\frac{50 \times \text{kg. of body weight}}{9}$

3. *For Children above the Age of 10 Years (or above 33 Kg. Body Weight):*

Total	
water	.. 20 to 30 cc. per kg. of body weight
Protein	.. 1.5 gm. per kg. of body weight
Carbohy-	
drate	.. 0.4 gm. per kg. of body weight
Fat (gm.)=	$\frac{40 \times \text{kg. of body weight}}{9}$

The basic physiologic water requirement must always be provided, but this varies so

greatly with muscular activity and changes in clothing and environmental temperature that only an approximate estimate can be made at first, final adjustments being made empirically. Impairment of renal function, acute infection, vomiting or diarrhea contraindicates restriction of the water intake. If the patient's caloric needs are too greatly exceeded by the contents of the diet offered, loss of appetite or nausea will interfere with the success of this form of treatment. If, after the first few months, the diet is gradually made less strongly ketogenic, it is compatible with normal health for a long time.

The use of the ketogenic diet is limited because of the practical difficulties of adhering consistently to a restricted dietary intake and because of the possibility of attendant emotional disturbances. It may be helpful for children who have frequent seizures which are not controlled by moderate doses of one or more of the anticonvulsant drugs, and then often in conjunction with them. The child and his family must be willing and able to accept the dietary regimen without emotional conflict.

**Prognosis.** Among the pertinent questions asked of the physician after the diagnosis of epilepsy has been established are these: What of the child's future? Is his mental development likely to be retarded by the disease? Will mental deterioration occur? Will his life be shortened by it? Should he attend school? Should he marry and have children? Such questions are probably best answered over a period of time rather than at the first visit. Usually the parents can be assured that the frequency of the seizures, especially those of the grand mal variety, can be reduced to a point at which they will not interfere seriously with the child's activity. By encouraging the parents to treat the child exactly as they would if he did not have the seizures, the personality changes can be largely avoided. Prognosis depends upon any coexisting mental retardation, physical handicaps, possible organic disease, and the adequacy of management, both medical and environmental.

Good control is difficult to define because it includes the child's social adjustment as well as reduction of the number of seizures. It is probably better for a child to have five or so major seizures a year and to be otherwise well adjusted at home and in school than to have only one a year, but to be so restricted in his activities that he becomes a social misfit. For example, parents may so restrict a child's activities that he makes few decisions

outside of their presence, and as he grows older his dependence on them continues.

The tendency to repeated seizures, with or without organic cause, is found in some families. A question by the parents or older children concerning the possibility of a convulsive disorder occurring in other children or in the offspring of affected persons is virtually impossible to answer accurately. In a general discussion of the problem it may be helpful to comment upon both the rare residual effect of a convulsion and the observation of Yannet that children who had parents with a history of a convulsive disorder were better adjusted and had fewer seizures than those children whose parents had not had seizures. Possibly such parents understand the problem more clearly.

Although it is probable that a severe prolonged seizure of one or more hours may deplete available stores of glucose and interfere with oxygenation and thus cause secondary cerebral changes, there is reason to believe that the usual convulsive episode does not cause irreversible damage. Convulsions followed by permanent hemiplegia are probably more often the result of a vascular accident which occurred before the seizure rather than during it. In such instances there are likely to be recurrent convulsions which are more difficult to control than those of idiopathic epilepsy.

Epileptic patients who are otherwise normal seldom die or sustain serious injuries as a result of their convulsive disorder.

Though the course of the disease varies in different patients, the tendency is for seizures to become more numerous unless the course is modified by therapy. A number of patients with unquestioned idiopathic grand mal epilepsy appear to undergo spontaneous cessation of seizures after adequate treatment. Patients who are well controlled medically rarely have seizures during their participation in athletic activities. The results of therapy are rarely satisfactory in infants and young children with infantile myoclonic seizures.

The prognosis for mental development in young epileptic patients or for mental deterioration in older patients has until recent years been gloomy, chiefly because opinion was based largely upon experiences with the more severe cases in public institutions. Collins and Lennox found the intelligence quotients of 100 children and 200 adults in private practice to average 109 with a range of 52 to 153 for the former and 47 to 139 for the latter. The intelligence quotient of those with evi-

dence of cerebral damage before the first seizure averaged 10 points lower than of those with idiopathic epilepsy. The highest scores were found in those with essentially normal electroencephalograms and in those with typical petit mal activity, the lowest in those having both grand mal and psychomotor attacks. With proper treatment most epileptic patients with normal mentality can be expected to maintain it.

## CHRONIC PAROXYSMAL DISORDERS

### SIMULATING EPILEPSY

#### NARCOLEPSY

Narcolepsy is a symptom complex characterized by recurrent diurnal attacks of irrepressible sleep, usually precipitated by a sudden emotional change. It is rare in children and is said to be more frequent in boys than in girls.

Narcolepsy has been classified according to etiology into "idiopathic" and "symptomatic" groups. Wilson has further subdivided the latter group into six categories: (1) toxic-infective, e.g., postencephalitic, (2) circulatory, (3) post-traumatic, (4) endocrine, (5) neoplastic, and (6) psychopathologic.

The attacks resemble those of epilepsy in their brevity, in the abruptness of their onset and in their paroxysmal and involuntary nature. The overpowering sleep of narcolepsy may come on suddenly while the patient is engaged in some activity such as talking, walking or driving. He then ceases what he is doing and falls "in a heap." The "sleep" is usually shallow, and the patient is easily aroused. The disturbance apparently has no relation to the physiologic need for sleep. Regular nocturnal sleep is normal. The patient exhibits mental alertness rather than somnolence after he has been aroused.

**Prognosis and Treatment.** The disorder tends to be chronic, but spontaneous improvement and cure are more common than in epilepsy. The amphetamines have proved much more effective than ephedrine. Dosage for a child should be established on the basis of the minimal amount which will produce the desired effect.

#### BREATH-HOLDING

See page 78. These spells, comparatively common in early childhood, are sometimes complicated by convulsions.

#### HYSTERICAL FITS

These can resemble true epileptic seizures in a superficial way. They are fairly easily dis-

tinguished by a number of characteristics. There is usually a typical neurotic background. Between attacks the patient may exhibit motor or sensory disturbances which do not follow the true neural patterns, and the gag reflex may be absent. Dilatation of the pupils and pallor of the skin and mucous membranes rarely accompany an attack. Loss of consciousness is superficial and variable. Sphincter control is not lost, and bodily injury from the seizure does not occur. Crying, moaning and disconnected talk throughout the attack, which may last half an hour or longer, are common. Hysterical patients, like other neurotic children with behavior problems, frequently show some abnormalities in the electroencephalogram. The treatment of hysterical seizures is that of the underlying psychogenic disorder.

#### SYNCOPE

Syncopal attacks of various types due chiefly to transient cerebral anemia are frequently complicated by slight tonic and clonic convulsive reactions of short duration confined mostly to the face and upper extremities. The most common form seen in early life is the *simple fainting spell*, which is brought on reflexly in certain children by a simple procedure such as removal of a sliver or insertion of a needle into the skin, or by a sudden fright or a painful stimulus while in a standing or sitting posture. The susceptibility to fainting in such children appears to be related to defective reflex regulation of the vascular system, which manifests itself as a sudden relaxation of the visceral venous system with bradycardia and a fall in blood pressure. Placing the patient in a horizontal position or with the head tilted downward at a 45-degree angle will tend to shorten the period of unconsciousness. When it is necessary to subject a child known to faint easily to some painful test or treatment, it is advisable to have him lie on a table during the procedure. Vigorous crying before and during a procedure, such as taking a blood sample, tends to prevent fainting. In an older child active gripping of some object and voluntary contraction of the abdominal muscles have the same effect.

In the *Stokes-Adams syndrome*, which occurs in heart block (p. 887), a short convulsive reaction often accompanies the syncopal attack. The latter appears within ten to twenty seconds after the onset of asystole. Syncopal attacks of a similar sort have been reported in patients as a result of *paroxysmal*

*tachycardia*, and attacks occur fairly frequently after muscular effort in young children with certain congenital anomalies of the heart, such as the tetralogy of Fallot.

A *hyperactive carotid sinus reflex* manifests itself by episodes of unconsciousness with or without brief tonic and clonic convulsive attacks. Fortunately this condition is extremely rare in children and is not more common among epileptic than among nonepileptic patients. Pressure over the carotid sinuses in the anterior cervical region causes a slowing or temporary arrest of the pulse in persons subject to attacks. Associated with the asystole are symptoms of faintness, weakness, loss of consciousness and finally the convulsive reaction.

## MIGRAINE

### (HEMICRANIA)

See also page 88. Migraine has long been regarded as being akin in some respects to epilepsy. The two frequently occur in the same family. Occasionally attacks of migraine are replaced by typical epileptic seizures in the same patient. Its paroxysmal character, its chronicity and its genetic features make migraine resemble idiopathic epilepsy. This has given rise to the unfortunate use of the designation "sensory epilepsy" as a synonym for migraine. In true visual seizures of epileptic patients the eye symptoms are much shorter in duration than they are in migraine and are bilateral.

# Mental Deficiency

Mental deficiency can be defined as inadequate mental development which may be expected to result in incapacity for independent social adaptation. It is a symptom of cerebral malfunction, many cases being associated with recognizable pathologic changes of the central nervous system. Though the subject will be treated here largely from the medical viewpoint, one must not lose sight of the fact that mental deficiency is a social as well as a biologic problem.

There are no comprehensive surveys to indicate the incidence of mental deficiency. In the United States there have been many large school surveys in which the estimated incidence of mental deficiency varied from 2 to 5 per cent. The number of institutionalized mentally defective persons in the United States approximates 120,000 (National Institute of Mental Health, 1947).

## PSYCHOLOGIC CONSIDERATIONS

Intelligence is not the result of a single mental process, but is made up of many different abilities, including abstract thinking, visual and auditory memory, causal reasoning, verbal expression, manipulative capacities, spatial comprehension and probably many others. This multifactor concept has been implied in the development of mental testing since Binet and the subsequent elaboration of the many varieties of psychologic tests. The present practice of quantitatively describing intelligence in terms of mental age, or intelligence quotient (I.Q.), which is the ratio of mental age to chronologic age, supplies an average of the composite attainments of most of these mental abilities. The practical success achieved by this method of grading intelligence results in great part from the fact that in the course of normal intellectual growth there is, as a general rule, a close correlation between the various mental processes. The degree, however, of intellectual defect associated with arrested or inadequate mental development is only rarely equally manifest

in each of the intellectual spheres. Frequently, especially in the less seriously retarded children, some of the mental functions may be well within normal limits. The importance of this concept in relation to diagnosis of mental deficiency becomes apparent when it is realized that the various mental abilities do not play an equal role in influencing subsequent social adjustment. Thus normal progress in academic schooling in the main depends on adequate development of such factors as visual and auditory memory, verbal facility and abstract reasoning. Other aspects of intelligence obviously play an important role in school progress, but defects of these are not nearly so much a handicap as are minor defects in the former. On the other hand, reasonable success in adjusting to many of the simple industrial disciplines in later life depends much more on aspects of intelligence related to visuo-manual coordination, spatial relationship, causal reasoning and other factors as well as to satisfactory personality characteristics. The relative value of comprehensive psychologic examinations must depend more on the broader concepts of the multiple factors in intelligence and its interpretation in terms of future social adaptability than simply on an estimate of average mental age.

For academic and administrative purposes the intelligence quotient is useful for classifying mentally defective children in regard to the degree of defect:

- I.Q. 51-75: moron, high grade or educable
- I.Q. 21-50: imbecile, middle grade or trainable
- I.Q. 0-20: idiot, low grade.

The proportionate distribution of these categories in the general defective population in England was estimated in the Wood Report as 75, 20, 5 for the moron, imbecile and idiot, respectively.

## CLINICAL CLASSIFICATION

The classification which follows is based on etiology and includes the most common recog-

nizable conditions in which mental deficiency is invariably present or occurs sufficiently often to rule out the possibility of random occurrence. The clinical conditions are grouped by the age periods in which the etiologic factors appear to be operative, namely, prenatal, natal and postnatal.

- I. Prenatal
  - A. Hereditary
    - 1. Familial mental deficiency
    - 2. Hereditary idiocy
    - 3. Phenylpyruvic oligophrenia
    - 4. Congenital ectodermoses (tuberous sclerosis, neurofibromatosis, cerebral angiomas)
    - 5. Heredo-degenerative cerebral diseases (see p. 1094)
    - 6. Cranial anomalies (primary microcephaly, craniostenoses, hypertelorism, congenital hydrocephalus)
  - B. Infection
    - 1. Congenital syphilis
    - 2. Toxoplasma encephalitis
    - 3. German measles
  - C. Maternal irradiation
  - D. Encephalopathy associated with kernicterus
    - 1. Rh, ABO maternal iso-immunization
    - 2. Nonspecific
  - E. Etiology not definitely established, or variable
    - 1. Mongolism
    - 2. Cretinism
    - 3. Congenital cerebral palsy
    - 4. Undifferentiated or primary amentia
- II. Birth trauma (anoxia, vascular injuries, phlebotaxis, and so on)
- III. Postnatal
  - 1. Central nervous system infections
  - 2. Cerebral trauma
  - 3. Cerebral vascular disorders
  - 4. Poisonings
  - 5. Recurrent convulsions

It is not within the scope of this section to discuss exhaustively all these conditions. Some are described elsewhere, and, for more complete descriptions of others, suitable references will be given.

FAMILIAL MENTAL DEFICIENCY

This category, from a sociologic viewpoint, represents the most important component of the mentally defective population. Numerically it is the largest group, comprising 35 to 45 per cent of all institutionalized defectives and probably about 60 to 70 per cent of all mental defectives in the community.

The diagnosis is relatively simple, depending on the presence of defective or inferior intelligence in one or both parents and in practically all the siblings, and on failure to find evidence in the history or physical ex-

amination of other causative factors. The mental status is almost invariably in the moron classification. There are no distinguishing physical characteristics, and the neurologic examination is essentially negative. The intellectual defect is most apparent in tests and situations involving verbal facility and abstract learning. The performance is on a much higher level in tests and situations dependent on manual dexterity and visuomotor coordination than would be expected from the verbal scores. Though this psychologic pattern is fairly characteristic of the familial type, it is by no means pathognomonic.

The nature of the hereditary transmission and genetic distribution is best described by reference to the following data from Halperin: Practically all the offspring resulting from a mating of two mentally defective parents of this category have defective or inferior intelligence. As the intellectual level of

PARENTS	NUM- BER OF CHILD- REN	DISTRIBUTION OF MENTAL STATUS OF SIBLINGS		
		Defec- tive	Infe- rior	Aver- age
Defective × defective	111	57%	39%	4%
Defective × inferior . .	81	35%	55%	10%
Inferior × inferior . . .	274	15%	57%	28%
Inferior ± average . . .	93	3%	33%	64%

From Halperin; Am. J. Ment. Def., Vol. 51.

either parent approaches the average, the proportion of children with defective and inferior intelligence tends to decrease. It is apparent that this type of hereditary transmission must depend on many independent genetic determinants whose effects are cumulative, rather than on a single abnormal gene as in most hereditary conditions.

These intellectually inferior individuals inherit the polygenic factors which determine their position in the lowest levels of the normal distribution curve of intelligence. In this sense these genetic factors may be considered "physiologic," in that they represent a part of the genetic pool which determines the hereditary transmission of normal intelligence. These individuals represent our intellectually marginal population, and their ability to maintain an adequate social adjustment will depend, in great part, on the nature, complexity and economic status of the environment in which they live.

# HEREDITARY IDIOCY

This category includes a number of genetically determined conditions that cannot be categorized on the basis of associated clinical symptomatology or laboratory observations as is true with the other genetic diseases to be described. Their recognition as a possible genetically determined condition must, therefore, rest on the birth of a sibling similarly affected for which no other adequate explanation is evident.

Genetically, the conditions are presumably transmitted recessively, since in all instances the parents have average intelligence. Consanguinity is occasionally present. As the designation implies, the mental level is usually low grade. The incidence of the condition cannot be estimated, since single cases in families cannot at present be recognized as belonging to this category.

## PHENYLPYRUVIC OLIGOPHRENIA (see also p. 259)

In 1934 Folling demonstrated phenylpyruvic acid in the urine of ten mentally defective patients. The incidence of the condition is difficult to determine. It occurs in about 1 per cent of institutional mental defectives. About 85 per cent of the persons with this metabolic defect have severe mental deficiency, being idiots or low imbeciles; practically all others are in the high imbecile or moron category. Rarely persons with average intelligence excrete this acid in their urine.

The enzymatic defect involves failure in the hydroxylation of phenylalanine to tyrosine. This results in accumulation of phenylalanine in the body fluids, which, after deamination, appears in the urine as phenylpyruvic acid. The amount of phenylpyruvic acid excreted seems to be related directly to the intake of phenylalanine. Since phenylpyruvic acid is excreted in fairly large amounts (0.5 to 2.5 gm.) with the ordinary diet, a random urine specimen is satisfactory for examination. When the acid is present, the addition of 5 to 10 drops of a 10 per cent ferric chloride solution to 5 ml. of urine produces a dark bluish-green color.

About 80 per cent of affected persons are blue-eyed and blonde, and many have eczematous lesions. Physical examination reveals no characteristic lesion of the central nervous system.

The inheritance of the condition depends on a recessive gene. Special diets with greatly reduced phenylalanine content have recently given some promise for preventing or mini-

mizing the cerebral damage in children with this condition, if started early in life.

## CONGENITAL ECTODERMOSSES (p. 1079)

This group, which includes tuberous sclerosis, neurofibromatosis and cerebral angiomas, has in common the presence of neoplasia or dysplasia in the central or peripheral nervous system and in other organs, as well as various skin manifestations. This group accounts for about 0.3 to 0.5 per cent of institutionalized mental defectives.

As a cause of mental deficiency, *tuberous sclerosis* (see also p. 1079) is the most important member of this group. The mental defect is not characteristic. The children are either of low imbecile or idiot classification. In infancy serious delay in mental development may be the only clinical manifestation, since other clinical features, namely, sebaceous adenomas, convulsive phenomena, cutaneous fibromas, shagreen skin, retinal lesions and extracerebral neoplasms, may be delayed in appearance or may not appear at any time. The disease may be suggested in a severely retarded child by the presence of circumscribed calcification in roentgenograms of the skull, usually in the periventricular areas. Retinal lesions are also important in infancy, since they may be the only physical manifestation of the disease. The most common one is the slightly elevated mulberry-like tumor mass, which is about twice the diameter of the optic disk and has a glistening, yellowish-white color. Convulsions are a fairly constant manifestation and often begin during the first year of life. They respond reasonably well to anticonvulsive drugs.

Genetically, the disease seems to be transmitted as a dominant character, since it is common to find incomplete forms in one of the parents, unassociated with mental defects.

Mental deficiency is an infrequent manifestation of *neurofibromatosis* (see also p. 1079), which is inherited as a dominant character. Neurofibromas may involve any nerve and vary in size from the smallest bead to grotesque overgrowth in extremities, resulting in symptomatic elephantiasis. Peculiar pigmentary lesions are seen in the skin, and there may be characteristic osseous defects. The type of mental defect varies from that of moron level to gross idiocy.

*Cerebral angiomas* (see *Sturge-Weber Syndrome*, p. 1080) is a rare cause of mental deficiency, which is usually of mild degree. This disturbance is hereditary, but the type of genetic transmission is not clear. Clin-

ically, it is characterized by cutaneous heman-  
giomas, especially of the face and forehead,  
associated with angiomatous neoplasia of the  
cerebral cortex. On the roentgenogram of the  
skull cerebral lesions have a characteristic  
type of curvilinear calcification. Convulsions  
eventually occur in most instances and are  
often difficult to control.

#### **CONGENITAL SYPHILIS** (p. 472)

Congenital syphilis is an uncommon cause  
of mental deficiency. In one institutional sur-  
vey less than two per 1000 inmates had  
definite evidence of central nervous system  
syphilis. The mental level is usually in the  
moron classification. Practically all cases show  
additional signs of neurologic abnormality in  
the form of spastic paralysis, incoordination,  
pupillary changes, and deafness. The cere-  
brospinal fluid in untreated cases is almost  
always abnormal.

#### **GERMAN MEASLES**

The importance of German measles in the  
mother during the first three months of preg-  
nancy as a cause of congenital cataracts,  
cardiac abnormalities, microphthalmos and  
deaf-mutism in the child is established. One  
of the less common developmental anomalies  
is microcephaly associated with severe mental  
retardation without microcephaly have also  
been reported.

Whether other types of viral diseases in the  
mother during the early months of pregnancy  
can injure the fetus so as to produce cerebral  
defects has not been established.

#### **IRRADIATION** (see p. 1371)

Pelvic irradiation of the mother during the  
early months of pregnancy may cause serious  
developmental malformations in the fetus.  
The severe mental retardation which occurs  
is usually in association with microcephaly.

#### **ISO-IMMUNIZATION** (pp. 335, 958, 1077)

The term "kernicterus" has been commonly  
used to designate the central nervous system  
lesions which occur as a complication of the  
hyperbilirubinemia associated with hemolytic  
disease of the fetus and newborn.

The pathologic and clinical manifestations  
of kernicterus are not confined to Rh or  
ABO iso-immunization. A variety of presum-  
ably unrelated etiologic factors in the neo-  
natal period are capable of producing the  
basic cerebral injury. These include severe

infections, dehydration and intestinal obstruc-  
tion. Prematurity greatly increases the likeli-  
hood of cerebral involvement. In all instances  
there is a definite elevation in the level of  
indirect serum bilirubin; the prophylactic  
value of exchange transfusion is related to  
reduction of it.

The term "kernicterus" indicates the strik-  
ing involvement of the nuclear masses of the  
basal ganglia; in most instances there is also  
involvement, however, either as yellow pig-  
mentation in the acute cases or as destructive  
changes in the chronic cases, of the medul-  
lary nuclei, optic nerves, fiber tracts in the  
spinal cord, dentate nuclei of the cerebellum,  
the hippocampus and the white and gray mat-  
ter of various cortical areas. Most children  
with kernicterus do not survive the neonatal  
period; those who do may exhibit a variety  
of clinical symptoms, including various mani-  
festations of cerebral palsy, mental deficiency,  
cranial nerve abnormalities particularly in-  
volving the optic and oculomotor nerves, con-  
vulsive disorders and aphasias. Mental de-  
ficiency, when severe, is usually associated  
with motor defects which may be hypertonic  
or hypotonic. Asymmetric spastic quadriplegia  
with athetosis is the most common pattern.  
Mental deficiency may rarely be the sole  
manifestation.

#### **MONGOLISM**

Mongolism is one of the most common of  
the classifiable categories of mental defect;  
Benda estimates an incidence of two to three  
cases per 1000 births. This category accounts  
for about 7 to 10 per cent of institutionalized  
mental defectives.

The cause is unknown, but two facts are  
definitely established. Although mothers of  
any age, including the very young, may give  
birth to a mongolian infant, the average ma-  
ternal age for such births is almost ten years  
greater than for random ones. Secondly,  
when mongolism is associated with twinning,  
both identical twins are almost always af-  
fected, and only rarely are both nonidentical  
twins. This fact, in addition to other observa-  
tions, suggests a dual etiology which includes  
both environmental and genetic factors. As-  
sociated noncerebral developmental defects,  
as in the heart, eye, external ear, distal  
parts of extremities and elsewhere, suggest  
that the disturbances in development in mon-  
golism are initiated between the sixth and  
eighth weeks of gestation.

Diagnosis depends on the presence of  
severe mental retardation associated with cer-

B

C

FIG. 332. A, The typical broad, spadelike hand of mongolism in a 12-year-old boy. Note the shortness of all fingers, especially the fifth. The presence of a single transverse palmar crease, instead of the 2 creases normally seen, is well shown. B, Roentgenogram of the hand of a 7-year-old girl with mongolism. Note the maldevelopment of the second phalanx of the fifth finger responsible for the shortening and incurving. The metacarpal bones and remaining phalanges also tend to be short and broad. C, The typical broad flat foot of mongolism in a 12-year-old boy. Note the wide space between the first and second toes.

tain pathognomonic clinical features resulting from a disordered growth of the skeletal system, especially of the skull and long bones. Findings resulting from defective development of other tissues and organs are frequently present. The disorder in the growth of the skull bones gives rise to most of the characteristic features. The skull is small, being usually in the tenth to twentieth percentile. It tends to be flattened anteriorly and posteriorly. The osseous orbits, as shown roentgenographically, are smaller than normal. There is a lateral upward slope of the eyes. An epicanthus (epicanthal fold) is present in the younger child which differs from that of Asiatic races by being confined

to the inner angle, rather than including most of the upper lid. The epicanthus tends to disappear after the tenth year of life. Chronic inflammatory changes involving the conjunctivas and lid margins are frequent. Cataracts appear in about 5 to 8 per cent of cases. Strabismus is common, as are developmental anomalies of the external ears. The tongue is usually protruded, owing as a rule to the smallness of the oral cavity. Sucking of it usually results in fissuring and furrowing (scrotal tongue) which does not become evident until about six months of age. The nose is short, with a flat bridge resulting from underdevelopment of the nasal bone. The teeth are delayed in eruption, small and ab-

FIG. 333. A, Roentgenogram of pelvis and hips of a normal infant at 9 months of age. B, Roentgenogram of pelvis and hips of an infant with mongolism at 7 months of age. The acetabular roofs are almost horizontal, and there is flaring of the ilia. These abnormalities may be measured as illustrated and as described by Caffey.

FIG. 334. Typical facial configuration of mongolism in a 7-year-old girl.

normally aligned as a rule. The neck is short and broad, and there is laxity of the skin at the lateral aspects. In the young child the abdomen is prominent, owing to hypotonia of the abdominal muscles. The extremities are shortened, especially the phalanges, so that the hands and feet tend to be broad, flat and square. The fifth finger is proportionately small, and tends to curve inward. Roentgenographic examination demonstrates that the second phalanx of the fifth finger is rudimentary in about 40 per cent of mongoloid children. The spaces between the first and second fingers and toes are increased. In the foot this is associated with a prominent skin crease. The genitals are poorly developed, and the secondary sex characteristics are delayed. An interesting observation is the straight, rather silky quality of the pubic hair. Alterations in the bony pelvis, recognizable radiographically in early infancy, have been described by Caffey. The ilia are broad, the acetabular angles are small, and the ischia are elongated.

The most frequently associated developmental anomalies are those of the eyes and heart; defects of the interventricular septum are the most common cardiac anomalies. Generalized hypotonia of the skeletal musculature is present, but wanes as the child becomes older.

Laboratory studies have not indicated any significant endocrine or metabolic abnormality.

The mental status is usually in the imbecile range, infrequently in that of idiocy or the moron level.

The emotional development of mongolian children is extremely simple. They are easily

Table 112. Differential Factors in Mongolism and Cretinism

	<i>Mongolism</i>	<i>Cretinism</i>
Recognizable . . .	At birth	After 2-3 months
Body growth . . .	Retarded	Retarded
Head . . . . .	Brachycephalic	Normal size
Eyes . . . . .	Upward, outward slant	Puffy
Osseous orbits . .	Smaller than normal	Normal
Epicanthus . . .	Present at inner angle	Not present
Nose . . . . .	Small; bridge underdeveloped	Normal
Tongue . . . . .	Scrotal; may protrude	Thick, large; protrudes
Hands . . . . .	Short; incurved 5th finger	Short; square
Feet . . . . .	1st and 2nd toes widely spaced	Short; square
Skin . . . . .	Occasionally dry	Very dry, pale, coarse
Hair . . . . .	Variable	Very dry and coarse
Muscle tone . . .	Poor; marked joint laxity	Unchanged
Constipation . .	Uncommon	Marked
Congenital anomalies . . .	Frequent: heart and eyes	Umbilical hernia
Ossification . . .	Slight or no delay	Marked delay
B.M.R. . . . .	Normal	Decreased
Serum iodine . .	Normal	Decreased
Cholesterol . . .	Normal	Increased

regimented and institutionalized. They are usually pleasant and affectionate, and rarely exhibit temper tantrums or behavior disorders. In the absence of serious extracerebral and cardiac defects, and when given reasonably good medical care, their life span need not be greatly shortened. Probably owing to the dryness of the skin and frequent fissuring and cracking of it during cold weather, erysipelas and furunculosis are more common than in normal children. The mongolian child is also more susceptible to infection of the upper respiratory tract, including the sinuses and middle ears, than is the average child, possibly because the abnormal skull development adversely affects drainage from these areas. There is, however, the usual response to antibiotic drugs. The incidence of convulsive disorders is about the same as in the general population.

The pathologic changes in the brain and spinal cord are not characteristic. Grossly, minor fissural and gyral deviations are noted. Histologically, there are minor changes in the ganglion cells, especially a reduction in number, as well as spotty areas of defective myelin formation. As in most conditions as-

sociated with mental deficiency, there is little correlation between mental capacity and pathologic observations.

The diagnosis of mongolism in the older child is relatively simple, but may present significant difficulties in the early weeks of life when most of the signs are not too obvious. The abnormal configuration of the skull, however, is established at birth, and the peculiar formation of the orbits and palpebral fissures are frequently the only specific findings on which a diagnosis can be based. Restraint in making a definite diagnosis during the first few months of life is wise, since occasionally facial appearances suggestive of mongolism occur in infants of normal intelligence.

The only clinical condition which may give some difficulty in *differential diagnosis* is cretinism (see Table 112), which usually is not manifest at birth.

There is no evidence that the *course* of mongolism is benefited in any way by the use of endocrine or other medications.

#### UNDIFFERENTIATED OR PRIMARY AMENTIA

This group includes patients with mental deficiency resulting from congenital cerebral abnormalities not classifiable in any of the recognized categories, either clinically or etiologically. Its relative importance is indicated by the fact that, in an institution admitting all types of mental defectives, this diagnosis was made in 6.5 per cent of the morons, 32 per cent of the imbeciles and 60 per cent of the idiots.

There are no characteristic physical abnormalities. There is frequently some increase in motor tone without palsy; the deep reflexes are hyperactive but equal; occasionally the Babinski responses are extensor, and extra-cerebral malformations occur in about 10 per cent of this group, the anomalies being located principally in the eyes and the skeletal system. Convulsive disorders occur in about 10 to 15 per cent of this group. The central nervous system at autopsy shows a wide variety of developmental defects, including malformations of gyri, distorted cellular architecture, absence or imperfect development of various cerebral structures, generalized or focal hypoplasias, and the like.

*Diagnosis* is made by exclusion of identifiable forms of mental deficiency.

#### BIRTH TRAUMA (p. 315)

Birth trauma is a relatively uncommon cause of mental deficiency; among 2000 admis-

sions to an institution caring for all types of mental defectives, only fifty-eight children (3 per cent) were considered to be defective as a result of birth injury. Most of them were in the imbecile and idiot categories, and about one third showed associated motor defects. Since the type of mental defect and of the motor defect when present are not characteristic, the diagnosis of birth injury depends on a careful birth and neonatal history.

#### CENTRAL NERVOUS SYSTEM INFECTIONS

(Nonsuppurative encephalitides, p. 546, purulent meningitides, p. 424; tuberculous meningitis, p. 469). Such infections account for almost 5 per cent of the admissions to institutions for mental defectives. There are all degrees of intellectual impairment, and associated neurologic abnormalities are frequent. A striking finding in those with minimal intellectual impairment is the relative frequency of severe behavior disorders, which often prevent adequate social adjustment and necessitate institutionalization.

#### RECURRENT CONVULSIONS (p. 1117)

Convulsive disorders are common among the various categories of mental defectives. In most instances the convulsions are an associated manifestation of the underlying cerebral pathology. Convulsions per se, however, recurring over a period of many years may *infrequently* be responsible for intellectual impairment. The mental status is usually in the moron category. The pathogenesis of the mental defect is not clear. In some cases frequent head trauma as a result of falls is considered significant. Continued exposure to adverse psychogenic factors with resulting psychotic deterioration undoubtedly also plays a role. Circulatory changes and other physiochemical abnormalities associated with the cerebral dysrhythmia have also been suggested as etiologic factors.

#### TREATMENT

A variety of organic methods to stimulate or accelerate the development of intelligence have been suggested. These have included glutamic acid, vitamin B<sub>12</sub>, various hormones and a surgical procedure for increasing cerebral blood flow. There is no agreement that any of them is significantly effective.

The care of the mental defective must be considered a joint responsibility of the home, school, community and state. Since these four

factors will obviously vary greatly from case to case, the subject can be discussed only in general terms. It is the responsibility of the physician, however, to translate these generalities into specific recommendations for the individual child. Defectives may be divided into (1) a trainable group, which includes most of the moron group and those of the upper imbecile level; and (2) a permanently custodial group.

**Trainable Group.** Except when there are serious emotional disturbances, most high grade mental defectives are educable and trainable for social adjustment to a partial or complete extent. The scholastic attainment should not be expected to exceed the fourth or fifth grade level. Specialized educational techniques are necessary for optimal development of limited abilities. Similarly, occupational training can be expected to result in definite but limited skills. As a rule, it is not the purpose of these specialized training programs to produce full-fledged employable artisans. Levels beyond the apprentice stage are rarely reached. The degree of occupational skill attained is not of primary importance, however. More useful is the inculcation of proper work habits, occupational interests and personality factors that make for cooperation with and trainability by future employers.

Training and education are best handled in the home and community, if possible. For most morons, community care will be successful under the following conditions: (1) The family accepts and appreciates the implications of the diagnosis of mental defect and the necessity for relatively long-term supervision. Someone in the family is willing to make the sacrifices the additional supervision requires. (2) There are facilities available in the community for the specialized types of education, training and recreation required by these children. Though these facilities, as a rule, are a part of the public school system, they are available in some private schools. The presence of associated motor defects, such as cerebral palsy or manifestations of convulsive disorders, will complicate the problem. However, the main consideration determining disposition of the case should be the intellectual impairment.

Institutionalization of mentally defective children should be resorted to only after home care has proved unsuccessful. It should rarely be necessary to remove the trainable defective from the community before early adolescence except to prevent the develop-

ment of serious emotional and behavior disorders resulting from inadequate home conditions. Under these circumstances foster homes, preferably in another community, should be considered.

**Custodial Group.** In the idiot child and those of the lower imbecile group, the problem is simply one of supplying satisfactory custodial care. The question of institutionalization, and when it should occur, is basically a parental decision, and only rarely the physician's responsibility. It will depend on such factors as (1) the economic status of the family and availability of space in a state-supported institution; (2) the presence of other children in the family; and (3) the emotional stability of the parents, especially the mother. The care required for a low grade defective infant is no more complicated or time consuming than that for a normal baby, and is frequently less. Other factors being suitable, it is poor judgment to recommend that these children be removed from their home during early life if the expense of institutionalization imposes a serious economic burden on the family. The presence of other children in the family, especially if they are relatively young, is not in itself an indication for immediate removal of the idiot child. Emotional disturbances of a significant degree rarely develop in normal children in families who continue to care for a low grade infant during the early years of his life if the parents are well oriented and emotionally adjusted. However, the emotional make-up of some parents, especially some mothers, is such that it is virtually impossible to care for a low grade defective infant in the home. The capacity of the family in this respect can usually be determined after a short trial period. As a rule, practically all mentally defective children of a low grade will eventually require institutional care, and provision should be made for it in most instances before the fifth or sixth year of life.

**Sterilization** represents an indispensable adjunct to a complete program of social care for the mentally defective. The place of sterilization in the over-all program should be clearly understood. Two distinct indications have been recommended for sterilization. One has to do with eugenic considerations. The other is primarily of social hygienic importance, based on the fact that, as a rule, the mentally defective person is unable to undertake the responsibilities of rearing a family. Although it is unlikely that the practice of sterilization will become widespread

enough to change significantly the incidence of defective genes, its value in the family with a hereditary type of defect is obvious and should be recommended. It is for social hygienic considerations that sterilization has its greatest value. Its use in this respect is generally confined to the high grade, moron female of childbearing age who does, or will, live in the community under reasonable supervision. State permissive laws vary widely, and a clear understanding of the legal aspects is necessary before the procedure is recommended. There is no evidence that the measure in any way leads to sexual promiscuity.

# Cerebral Palsy

The term "cerebral palsy" as currently used includes a group of nonprogressive disorders resulting from malfunction of the motor centers of the brain, characterized by paralysis, weakness, incoordination or other aberrations of motor function, which have their origin prenatally, during birth or in the first year or two of life. Cerebral palsy encompasses the neuromotor manifestations of organic brain damage and occurs in conjunction with other manifestations of it such as seizures, mental retardation, various sensory defects and behavior or emotional disorders. It is not a specific type of brain damage, but it results from congenital defects, mechanical and chemical injury and infection. The pathologic and clinical findings are varied. It is a nonfatal (*per se*), noncurable condition that is frequently amenable to therapy and training.

Cerebral palsy is one of the leading causes of crippling in children; it is estimated that the prevalence rate is 100 to 600 cases per 100,000 population, the majority of known patients being under twenty-one years of age. The care and support of these children, who usually have multiple handicaps, represent an important economic and social as well as medical problem.

John Little's description of spastic quadriplegia in 1862 is still classic. Minear's recent classification of cerebral palsy (Table 113) is of value, since its use emphasizes that the term is not a diagnosis and that there are varied causes, manifestations and degrees of involvement. The information necessary to classify a given child plus a knowledge and understanding of his family's capabilities and limitations should lead to a rational therapeutic approach.

*Spasticity* is characterized by the pathologic stretch reflex, increased activity of deep tendon reflexes, clonus, scissoring and contractures affecting the antigravity muscles. Among early signs are fixed posturing, often opisthotonos or maintained partial tonic neck responses. Sudden lifting of the child may produce scissoring of the legs. Tonic neck

reflexes are too readily elicited or are asymmetric, and the trunk and pelvis may fail to follow the head. Stepping and placing reflexes are absent or done better with one foot than the other. Lifting the supine child with a hand under the occiput produces extension of the neck and retraction of the shoulders. In the prone position protective turning of the face does not occur, and the child remains nose down.

*Athetosis* is marked by involuntary incoordinate motion with varying degrees of muscle tension. Reflexes are usually normal. Initially the clinical manifestation may be one of hypotonia, and only during the second year may the fine wandering movements of the fingers, hands and feet become evident and develop into the typical pattern of athetosis.

*Ataxia* is manifest by lack of coordination due to disturbances of the kinesthetic and balance senses. There may be associated hypotonia.

*Tremors* may be intentional or involuntary motions with a rhythmic pattern.

*Atonia* or *hypotonia* is characterized by soft muscles and usually by increased deep tendon reflexes. It frequently is a precursor of other types of involvement. Disturbances of muscle tone are present in almost all types of involvement.

Mixed types are seen, but usually one form predominates. Spasticity is the most frequent type and together with athetosis accounts for approximately 75 per cent of all cases; seizures occur in approximately 25 per cent and are frequently of the myoclonic type in infancy.

**Diagnosis.** Early diagnosis of brain injury is important to the child and his family, since many of the physical and psychologic complications can be decreased or avoided if parents are given help and guidance during the first year or two of the child's life.

When one manifestation of brain damage is recognized, others should be suspected. Children who have a history of any of the factors outlined above should be observed carefully for abnormalities. The presence of

Table 113. Classification of Cerebral Palsy

- 
- I. Physiologic (motor)
    - A. Spastic
    - B. Athetotic
      - 1. Tension
      - 2. Nontension
      - 3. Dystonic
      - 4. Tremor
    - C. Rigidity
    - D. Ataxic
    - E. Tremor
    - F. Atonic (rare)
    - G. Mixed
    - H. Unclassified
  - II. Topographic
    - A. Monoplegia—involves one limb; condition is rare; should be checked closely to determine whether one is dealing with a paraplegia or hemiplegia
    - B. Paraplegia—involves the legs only and is practically always of the spastic or rigidity type
    - C. Hemiplegia—lateralized half of the body is affected, and it is usually spastic, although pure athetoid hemiplegias are occasionally seen, as are pure rigidity hemiplegias. There is often sensory involvement in the areas of proprioception to point discrimination and form perception. Aphasias appear more frequently in right than in left hemiplegias and are much more common in acquired than in congenital cerebral palsy
    - D. Triplegia—involves 3 extremities, usually both legs and one arm, usually spastic. This may represent hemiplegia plus paraplegia, or incomplete quadriplegia. In the latter case both arms will be equal or nearly equal in length. In the former the involved arm will be shorter
    - E. Quadriplegia (tetraplegia)—involvement of all 4 extremities. Patients with the greatest involvement of the legs are usually spastic, and patients with greatest involvement of the arms are usually the dyskinetics, including athetoids
    - F. Diplegia—this term is seldom used. "Paralysis affecting like parts on either side of the body; bilateral paralysis" (*Dorland's Illustrated Medical Dictionary*, 23rd ed.)
    - G. Double hemiplegia—this term is seldom used. "... implies those cases in which the arms are more involved than the legs. These are usually spastic in type" (Cruikshank and Raus: *Cerebral Palsy—Its Individual and Community Problems*. Syracuse University Press, 1955)
  - III. Etiologic
    - A. Prenatal
      - 1. Hereditary—genetically transmitted and may involve racial or familial predilections and often sex-linked. These are often classified as "cerebral agenesis." The symptoms are often present at birth and generally do not progress. Examples: hereditary athetosis, familial tremor, familial spastic paraplegia
      - 2. Acquired in utero
        - a. Prenatal infection (toxoplasmosis), rubella or other maternal infection
        - b. Prenatal anoxia—carbon monoxide, or strangulation of mother, maternal anemia, hypotension, e.g., following spinal anesthesia, placental infarcts or placenta abruptio, kinking, knots or prolapse of the cord
        - c. Prenatal cerebral hemorrhage—maternal toxemia, direct trauma, maternal bleeding diathesis

  - Class C. Patients with cerebral palsy who need bracing and apparatus and the services of a cerebral palsy treatment team
  - Class D. Patients with cerebral palsy limited to such a degree that they require long-term institutionalization and treatment

any anomaly or of disturbances during the neonatal period such as feeding problems, irritability or drowsiness, cyanosis, jaundice, respiratory difficulties, abnormal muscle tone or seizures should lead to a careful observation of the central nervous system.

The cases of more severe damage or deficit are usually apparent early in life. Those of less degree should be suspected when there is a significant deviation from normal rates of growth and development or when there is persistence of infantile physiologic reflexes such as the Moro and the tonic neck ones. The typical adult neurologic patterns may not develop during the first year or two of life even though the lesion is present from birth or earlier. Definite handedness apparent before twelve to fifteen months suggests hemiparesis.

The differential diagnosis may include consideration of more acute conditions such as trauma to the brain or the peripheral nerves, poisoning, infection or tumor of the central nervous system, degenerative diseases, Sydenham's chorea, amyotonia congenita and muscular dystrophies. It must be remembered that in children with motor dysfunction associated with organic brain damage the other manifestations such as seizures, retardation, sensory and perceptual changes and abnormal behavior are also frequently present.

**Prognosis.** Prognosis is dependent on a careful appraisal of all factors related to the individual child, his family and the community. With the knowledge that the basic defect cannot be cured, that associated or complicating conditions are usually present, that social, economic and psychologic factors are usually harder to control than the medical ones, the outlook for the group as a whole is not favorable for self-sufficiency or ability to compete with peers. Only a small percentage of affected children achieve independence and a satisfying way of life. The goals should be much lower in the majority of cases, and only by observation of growth and maturation, by response to treatment and training and appreciation of the child's and the family's ability to use their own and the community's resources can a realistic goal be set. In general the child's intelligence is the best prognostic guide, so that use should be made of the best psychometric help available.

**Treatment.** The general features of management of a handicapped child are described elsewhere (p. 1145); these include a realistic short- and long-term plan, assistance to the child in making full use of his residual assets,

avoidance of secondary emotional problems, support and counseling for the family and use of available community resources. The goals must be reviewed periodically in the light of progress made, and therapy must be timed in accord with the child's developmental status. In general the aim of treatment should be to secure for the patient a happy childhood and a well adjusted adult life in which he performs well within the limits of his capabilities.

In the most seriously involved children, treatment may be largely supportive and aimed at prevention of complicating factors such as contractures, nutritional deficiencies, pressure sores, infections and emotional problems in all concerned.

If the child has intelligence enough to try to learn, efforts at developing muscle strength, balance and coordination, functional posture and skills in communication and self-help should be made. Since it is usually impossible to evaluate accurately the relative detrimental effect of several handicaps, all defects that lend themselves to correction should be treated. The total benefit of such efforts frequently is rewarding, although there are few well controlled clinical trials of any individual therapeutic regimen or combination of therapies to which such children are exposed.

The group that appears least seriously involved may not reach its full capability because of lack of attention to emotional factors that may be more handicapping than the motor defect itself.

More than anything else, the handicapped child and his parents need the continuing care of a physician whose judgment is not blurred by too close contact with individual parts of the problem. The child with cerebral palsy has an injured brain whose function is not that of the normal brain. Child and parents must not be allowed to succumb to a well meaning but tyrannical optimism aimed at improved performance of individual functions, but disregarding the limit set for the whole child by his organic handicap. The desired end result of a happy adult, well adjusted and performing at his maximal ability, is best reached by early recognition of the extent of his handicap, and kindly but realistic direction toward attainable rather than unattainable goals. Acceptance by child, parents and physician of that part which cannot be altered should be achieved at least by the time of the early school years. Planning for adult life on these terms accomplishes more for the child and his parents than all the

mechanical gadgets, therapies and surgical procedures known to medicine.

The specific treatments for various manifestations are discussed elsewhere.

The orthopedist is concerned with developing and maintaining good body mechanics. This is accomplished by bracing, by physical therapy and by surgery that is largely limited to tendon lengthening, to arthrodeses and to muscle transfers in older children.

Training resulting in functional improvement of body mechanics, muscular control, gait, use of hands, and in verbal communication can be effectively carried out by parents under the direction of physical, occupational and speech therapists. Success is proportionate to the degree of physical, mental and emotional involvement of the patient, to the therapist's understanding and use of physiologic approaches and to the integration of such therapies with other services for the child.

Physiotherapy, most of which can be carried out by the parent (after instruction), should be begun in infancy to avoid development of contractures and to stimulate control of movement. The joints involved—usually ankles, knees, hips, wrists and fingers—are manipulated against the direction of maximal contraction and are finally carried through a full range of movement. Short periods of therapy repeated at intervals during the day are more effective than fewer long sessions; the procedure benefits the child physically and the parents emotionally. Active motions should be encouraged. Later, efforts at improving coordination by use of games, peg boards, training in sitting and standing in supportive chairs or at stand-up tables, walking aids such as parallel bars, skis or crutches may be added as indicated under guidance of trained therapists.

At present few therapists are available in cerebral palsy clinics, so that the individual child often gets only scanty attention. Most of the procedures are relatively simple, and most of the equipment easily constructed by amateurs. Enthusiasm for clinic care should

not overlook the powerful and much more available resources within the home. Parents should be trained and encouraged to carry out as much of the therapy as possible.

Neurosurgery may play a part in a small number of cases. Treatment of subdural collections of fluid, hydrocephalus, craniosynostosis, intracranial vascular anomalies or hemorrhage and acute trauma may play a part in modifying or preventing some of the conditions that lead to cerebral palsy. Various procedures aimed at removing foci or at interruption of pathways in the brain to reduce uninhibited activity are under clinical investigation.

Children with visual, auditory and dental problems are handled essentially as are other children with such problems with appropriate modifications for their associated disabilities and limitations.

Many drugs having varied pharmacologic actions have been used, and others are under current evaluation. None has satisfactory clinical effect without significant disadvantages. Of the newer ones, meprobamate for athetosis and zoxazolamine for spasticity appear to be occasionally helpful in diminishing symptoms, but not in improving function. Various tranquilizers relieve secondary tension and may help at times to improve over-all function. Anticonvulsive drugs should be used as indicated (see p. 1123).

**Prevention.** A review of the many causes of brain injury listed above reveals a number which are preventable. The practicing physician can make a major contribution by applying known principles of preventive and therapeutic medicine.

# Behavior Problems Associated with Organic Brain Damage

Those who participate in the care of brain-damaged children are aware that behavior problems represent a significant part of the problem.

The term "brain-injured child" unfortunately has become rather widely used for a syndrome of abnormal behavior and distorted learning patterns in children with presumptive or demonstrable brain damage. It is a misleading term and does not apply to all children with central nervous system injury or defect.

This syndrome may occur in conjunction with motor and sensory defects, with seizures and with significant delay in the rate of mental development, or may appear as the only apparent manifestation of brain damage. The characteristic symptoms are unpredictable variations of behavior, distractibility or short attention span for the age (or the converse—perseveration), hyperactivity, impulsiveness, irritability, over-reaction to environmental stimuli and eventually difficulties in abstract thinking.

None of these alone is of diagnostic significance, but when several appear together in a child, the disorganization and weakened controls suggest a basis in brain damage. The child's behavior varies from day to day without relation to other recognizable factors and is apparently as unpredictable to himself as to others. His restlessness is frequently marked by running to and fro, by constant physical activity and by a short attention span for any one activity that is not consistent with that seen in others of his age. His enthusiasms are tense but short, and his acts appear to follow no pattern of thought. He tends to react violently to frustration and to other stimuli, and he may be a constant storm center in the family, at play or in school. It is not so much that any single part of his behavior is bad, but rather that there is always too much of it. At school age, although

frequently of normal or borderline intelligence, he usually has difficulty with number concepts, with associating the particular with the general and with drawing logical conclusions from abstract material. Allied to the problem of handling abstract concepts are problems in the child's perception of the world, so that instead of attending to the whole of the environment he perceives, he may attend only to a minimally important part. The ordinary relationship between figure and background in perception is lost or confused so that the child's reaction is frequently unpredictable.

As the child grows older secondary behavior manifestations related to his frustrations, to how he feels about himself and to his contacts with people may obscure the earlier pattern. In many cases these secondary symptoms appear as emotional immaturity, anxieties and fears, school failure, and the like. In the individual child it is not easy to distinguish the basic symptoms related to brain damage from the acquired ones.

There are all degrees of the condition, and there are no clear-cut diagnostic aids. The syndrome should be suspected in any child with abnormal behavior who shows clinical evidence of brain damage or whose history includes events potentially leading to sequelae in the brain. The postencephalitic or post-traumatic behavior of some children is an example of this condition in which hyperactivity is a major symptom. Many children do not show any abnormality on careful neurologic examination. Some are clumsy and maladroit in voluntary activity as compared with their contemporaries. Handedness may develop late.

Abnormalities may or may not be detected by electroencephalography, by pneumoencephalography or by cerebral arteriography, but none is accepted as being specific for the syndrome. There is suggestive evidence that

the lesion, if localized, may be in the mid-brain.

Psychologic test performance frequently gives a clue to the presence of disorganization, weakened controls and poor power of inhibition. The "organic picture" may be suggested by an experienced clinical psychologist from interpretation of the Wechsler Intelligence Scale for Children (in particular the child's approach to the visual-motor tasks), the Bender-Gestalt Motor Test, the Werner-Strauss Marbleboard Test and the Rorschach Test. There appears to be little correlation with the intelligence quotient except as this is influenced by other complicating factors. The great variability in function displayed by these children is a clue to the problem.

The syndrome of behavior problems associated with brain damage should be distinguished from mental retardation, psychoses and severe secondary behavior problems arising on a psychodynamic basis.

**Treatment.** The management of children with behavior problems resulting from brain injury should be directed toward helping the family and others associated with the child to understand him and thus minimize secondary behavior problems. Parents frequently are put at ease if behavior is explained on the basis of a physical problem rather than as a result of parental incompetence. They can meet the prolonged dependency needs by treating such children as though they were at a younger age level. The erratic behavior and lack of self-control point to the need for definite limits and consistent controls and discipline. Firm constructive guidance is much better than permissiveness. Psychiatric treatment when available may be as helpful with the management of such problems as of those on a purely psychodynamic basis.

In addition to personal support and understanding of the child and his parents medication is sometimes a helpful crutch to modify the extremes of behavior. Success in prolonging the attention span and in leveling behavior is reported with use of the amphetamines. Dextro-amphetamine, 5 to 10 mg. in the morning, or twice that amount of amphetamine sulfate may be tried. Various tranquilizing agents may modify the irritability

or decrease the impulsiveness. Reserpine in doses of 0.1 mg. two or three times a day may be increased to tolerance (as much as 4.0 mg., three times a day). Chlorpromazine, 10 to 25 mg., two or three times daily, and captodiamine (Suvren), 50 to 100 mg., three times daily are sometimes of value. The anticonvulsive drugs are of minimal help in modifying behavior, and the use of phenobarbital may have a stimulating effect on children with such behavior problems.

The physician should guide the family to experts in the field of special education. The contributions to the educational phases of this subject by Strauss and Lehtinen and by Lewis should be of aid to families and to teachers. Modification of school curricula and techniques by placement in small classes, individual attention (concrete materials in teaching abstractions) and by elimination of distractions are said to be helpful.

**Prognosis.** The outlook for such children appears to depend principally on the attitudes and guidance of those who deal with them and on the degree of success which can be achieved in daily living and social contacts. Many are failures because of the complicating secondary behavior problems attributable to disruption of family life and to social unacceptability. Some become delinquents or are placed for care in institutions for mental defectives or psychotics. Some level off during adolescence and appear to achieve a comfortable way of life in relatively nonrestricting activities.

# The Physician and the Child with a Handicap

It has become increasingly important for the physician who cares for children to become familiar with the special problems of the child who chronically deviates from normal because of some congenital or acquired disability.

The successful management of such a child depends more often on the social adjustment that can be made than on purely technical procedures. The following general principles apply especially to children with various types of brain injury and to a less degree to all children with handicaps.

**The Physician.** Some physicians are not geared to provide adequate management for the handicapped child and his family. Care of long-term illness does not provide the reward to the ego which accrues from the management of self-limiting or readily curable disturbances. Management is time-consuming, and many of the children are "uncooperative." They disrupt a busy appointment schedule, and much time must be spent with emotionally disturbed parents. However, the physician who extends his responsibility beyond the treatment of the "chief complaint" will find rewards in helping the young handicapped patient and his family to live more comfortably with a long-term illness.

A physician may feel inadequate because the complexity of the problems makes them appear unsolvable or beyond means at his immediate command. He must be able to utilize other professional disciplines and other resources in the community while he maintains his own professional relationship with the family. Abandonment or rejection of a handicapped child by a physician by ignoring the real problem, by giving the family false hopes or by not seeking help which is available only compounds everyone's difficulties. A physician may feel threatened if a specific etiologic diagnosis cannot be made or if the evaluation cannot be completed at one visit.

Intelligent management *can* begin at the first meeting with the family and with a simple functional appraisal of the child.

The physician who cannot be a patient, noncritical listener, who cannot be satisfied with small gains, who cannot project himself into the child's and the parents' position sufficiently to offer intelligent support when a cure is not available, who clings to outmoded concepts and is not realistically aware of both the possibilities and limitations of habilitation, who cannot or will not work with others in the community, and who does not provide adequate general pediatric care at all times, should not complain if others take over where he has failed.

**Management of the Child.** By continuing contacts with the child and his family the physician can help in formulating both a short- and a long-term plan that is realistic for all concerned. He should help the child make use of his intact ability as effectively as possible and become as socially acceptable and self-sufficient as his limitations permit. The child with multiple handicaps is rarely capable of achieving a great degree of independence. The physician must, on occasion, interpret the child and his behavior to those who are in regular or occasional contact with him. A physician should make every effort to minimize the secondary handicaps in the field of personality development so that they do not become more serious than the primary defect. He should above all else try to help the child lead a happy and useful life.

**The Family's Problems.** Since the child's environment and the emotional climate of the home are of equal if not greater importance than the medical care per se for the child's eventual adjustment, every effort must be made to assist the family to understand their own reactions and to fulfill their own tasks. Parents' reactions to a defective child are varied, depending on the extent to which they

feel their competency, social standing and anticipated way of life to be threatened by the handicap. Most parents initially attempt to deny the reality of the defect, particularly if it is one that is not obvious physically. This stage is usually followed by one of frustration and disorganization in which all sorts of fears about the future become overwhelming. Simple explanation, support and guidance for the family are particularly necessary during this stage. Depending on the degree of maturity and emotional resources of the family, they can be helped to accept their problems realistically and to plan constructively for the long-term needs of the child.

The types of problems are as varied as the people involved. Most parents, regardless of their background, have feelings of guilt about the defective child which must be resolved lest attitudes of self-sacrifice, excessive overprotection or rejection of the child develop. Most families develop ambivalent feelings about the child, varying from overt hostility to gross overindulgence. The establishment of limits of acceptable behavior and the consistent teaching of discipline which are so important to a child's emotional development are thus lacking. The handicapped child frequently may be the precipitating factor of marital difficulties which are not basically related to him.

As the child grows older the parents have to accept many roles, and make psychologic adaptations which would otherwise not be necessary, because of the child's prolonged dependency upon them. The problems of social isolation, sexual development and unpleasant behavior become increasingly important to the family as the child grows older.

**Family Therapy.** Parents in retrospect often complain that the status of the child was not made clear to them, that the diagnosis was based on an incomplete examination or hasty judgment, that poor prognosis was not justified or that their part in helping the child was not explained. It must be remembered that many parents hear, retain and comprehend only in part, so that various interpretations must be given in an acceptable and understandable way to those concerned. The initial explanation of the facts about a child with a handicap should be made to the parents *together* in as simple a way as possible. Technical explanations are only confusing. Long-term prognosis and planning should be left for a later interview, and emphasis should be on management of immediate prob-

lems and symptoms. Questions should be answered simply, reassurance given to minimize guilt feelings, and the importance of time in determining the developmental ability of the child stressed. Attention cannot be given too early to the avoidance of secondary emotional problems in the child and his family. The practical problems of carrying out the home program can best be appreciated by a visit to the home.

A physician who is not aware that the parents' feeling of guilt about the child may be projected to him will be unprepared to act with the necessary understanding and patience and will emerge with a bruised ego. Guidance and support to the family is a continuing affair, and acceptance of the handicapped child is probably never fully accomplished by the parents because the problems change with advancing age.

Care should be taken to assure the siblings an equal share of the parents' time, attention and interest. With neglect their problems may become greater than those of the affected child. Their questions about the abnormal child should be answered simply and honestly. The experience of living with a seriously handicapped brother or sister may be used constructively to teach tolerance, patience and understanding of others. If parents openly accept the child as an individual, despite his limitations, a good example is set for others in the community. This is the best method of "public education." The converse is also true.

The question of the probable outcome of future pregnancies is frequently raised by parents. If the cause of the disability is clearly an accidental one, it is easy to be reassuring. If it is known to be genetically determined or to arise as a result of circumstances that might be repeated, the physician should explain the facts as simply and clearly as possible and help the parents to make their own decision based on available evidence (see p. 247). When the family have made their decision on grounds that are valid for them, the physician should support them in it.

**Institutional Care.** In the case of a seriously involved child who will always be completely or partially dependent on others for his care the question of care away from home will arise. The physician should help the family to make their own decision about this by objectively discussing with them the advantages and disadvantages of such care. The decision is the family's and not the physi-

cian's, although he may diplomatically initiate the discussion if he is convinced that such a solution is beneficial to all. Current concepts emphasize the potential value to all concerned of home care during infancy and early childhood. Even severely handicapped children can profit by tender loving care at home; mongoloid children in particular have a much greater potential if given good care in the average home than if placed in an institution at birth.

It is often said that defective children should be placed away from home at birth lest the parents become abnormally devoted to them. This may occur when feelings of guilt are not relieved, but the average family with guidance can handle such children to advantage at home for a few years. Parents in general feel more comfortable about later placement if they gradually gain acceptance of the child's limitations by normally fulfilling their role as parents. Too early placement may lead to doubts and greater feelings of guilt.

Temporary placement away from home is indicated when the child himself can profit by greater opportunities in a different environment or when inevitable family emergencies arise. If the defective child becomes a serious burden to the physical or emotional health of the parents and siblings, a change should be made. Placement is wrongly used as an escape from the physician's or the family's responsibility. It is usually not wise to encourage brothers and sisters to assume the permanent care of a dependent child.

**Use of Community Resources.** The physician should make effective use of local community resources such as public health nurses, baby sitters, "home maker" services, day care centers, social agencies, voluntary health agencies and temporary boarding homes to give the family a vacation or to tide them over emergencies. The physician often overlooks the support which the church can give to families in times of stress. A religiously oriented parent is better able to accept the burden of a handicapped child than one without such a resource. Better communication between the clergy and the medical profession can lead to more effective family counseling.

In less severely affected children the physician should assist the family to get appropriate help from public or private schools that may offer programs for "exceptional children." An increasing number of classes for orthopedically, mentally and emotionally

handicapped children, as well as for those with visual and hearing defects, is being provided by the public school system in many states.

Most communities, encouraged by voluntary health agencies and by parents, are developing services of some sort for various categories of children with handicaps. These include medical facilities for early diagnosis, evaluation and treatment, social case work, home care by nurses, psychologic evaluation and counseling, baby sitting or temporary home care, educational and recreational facilities, occupational training, sheltered workshops and residential training or supportive care. None of these threaten the physician, but add to what he himself can do for the patient. Since many of these services are necessary regardless of the cause or name of the disability, it is incumbent on the physician as a community leader to encourage their development and use for all children who need them regardless of the category of handicap.

**Parent Organizations.** Parents' lay organizations can be helpful in affording those with common problems an opportunity to share their anxieties and to gain strength and hope through identification with a group. Efforts in behalf of community education, support of research and voluntary participation in medical services can be psychologically important to parents and constructively helpful to the community.

# Psychoses

Mental illness of this type is uncommon in children. It is always difficult to diagnose, because the normal child shows many behavior traits which at another age indicate psychopathology. It is important that all psychiatrists have an adequate knowledge of the behavior of normal infants and children to help them in problems of differential diagnosis. Similarly, it would be well if the pediatrician had greater experience with emotionally disturbed children so that he could distinguish between deviant and normal behavior. He errs frequently in failing to recognize mental illness until it is well advanced.

**Etiology.** It is not clear to what extent heredity plays a part. The environmental stresses and strains are more readily understood. Some children appear to be constitutionally susceptible to unhealthy life situations, and the combination of environmental plus constitutional elements predisposes to illness.

**Clinical Manifestations.** One of the most frequent forms is an *acute delirious state*, which may even become maniacal. This condition is encountered most often with acute febrile disorders. Mania may also develop as a symptom of chorea, hysteria or epilepsy.

*Manic-depressive insanity* may occur in children, sometimes in a minor degree which resembles merely exaggeration of the ordinary moods common to most children and adults. It may take the form of depression with a feeling of despondency and physical inertia, but it may proceed to attempts at suicide.

*Schizophrenia (dementia praecox)* is the most frequent of the psychoses beginning in early life. Until recently it was believed that this psychosis developed only in certain types—the quiet, shy, “model” child who was often an exceptional student. Now we are inclined to believe that there are no sure prognostic signs before twelve years of age. Beyond this age it is well, however, to note any tendency to “brittleness,” to a certain unyielding inability to adjust to differing personalities or standards, to a sort of intolerance of any but the child’s own mode of life. With

this change there appears a growing ritualism—certain hours for doing certain things, unusual orderliness, inability to make sudden new plans or decisions. In various ways the schizoid child begins to draw a veil between himself and others. This is a deep sort of reserve which seems to have only those fleeting contacts with reality that one has when he is extremely sleepy, so that he is constantly slipping away into a dream state. There develops a splitting between the content of an act and the act itself—silly laughter with some tragic statement, or tears or rage accompanying some trivial act. Dilapidation is a pretty strong word for what begins as a sort of moth-eaten existence—carelessness, sloppiness, perennial tardiness, satisfaction with empty activities or just sitting. The ritualism earlier expressed in careful dress and behavior now is manifest in more bizarre matters—always getting out of the same side of the bed, always chewing the food for a given length of time.

The physician may know such adults who are apparently happy and successful. The schizoid type of personality is indeed common, nor do we know why in some instances it goes irrevocably on to overt disease. It requires the greatest understanding to know when to warn a family that disaster lies ahead and that therapy is indicated immediately, in contrast to a situation in which irreparable damage would follow the diagnosis of incipient insanity in a formal, brittle, conforming, non-adventuresome type of person.

Schizophrenia is a term which covers a number of distinct clinical patterns which are possibly much less disease entities than they are surface phenomena. Two definite types are discernible in adolescence. In one the child seems rapidly to lose interest in his surroundings. In this *hebephrenic reaction* the child begins to lie in bed through the morning, to lose interest in appearance, to be dull and lethargic in all his actions. He does not make any effort to explain or excuse his new attitude and gradually sinks into a vegetative existence. The second type is *simple*

*dementia praecox* in which there are less marked but similar symptoms and to which are added many bizarre delusions centering usually about the problems of sexual adjustment. Thus the boy will follow in minutest ritual certain diets or exercises to restore a fancied loss of sexual power. Proposals of marriage to complete strangers or terrific despair over the bad effects of masturbation appear. Bizarre sexual delinquencies, particularly involving younger children, occur. For both the hebephrenic and simple types there is usually about a two-year prodromal period of mild depression in which suicide is not uncommon.

*Paranoid dementia praecox* tends to develop later in life. *Catatonic dementia praecox* also is uncommon in childhood.

*Infantile autism* is manifest at an early age, and sometimes even at birth the infant seems different; he never develops much capacity to relate to other human beings. Such infants have normal physical development, but fail to develop speech and affective relations with parents at anticipated times. They differ from older schizophrenics in that there is no abrupt change in behavior. Sometimes they appear deaf, but without measurable clinical evidence to support a diagnosis of deafness. There may be smiling which seems inappropriate to the occasion. A tendency to destructiveness is often manifest. For example, when older, they may show an interest in mechanical gadgets by taking them apart, but have no interest in reassembling them. Toilet training is delayed at least several years, and

social relations with other children are never satisfactory.

The *prognosis* is poor, even after institutional care or shock therapy. Individual care provided by friendly and accepting adults who are able to give their undivided attention brings the greatest response from the child, but this is usually too time-consuming for the average parents.

**Differential Diagnosis.** This is extremely difficult, since there is no symptom of any psychosis which a perfectly normal adolescent youngster cannot clearly manifest at some time. The physician should know that, although the chances of a psychosis developing are extremely small, he must be aware of such a possibility.

**Prognosis.** The separate attacks of manic-depressive insanity have an excellent prognosis. The acute delirious states accompanying infections also have a good prognosis. Until recently it was thought that the prognosis in *dementia praecox* was always bad. New forms of treatment (shock therapy) with adults, particularly when used in the early stages, seem promising, but many psychiatrists are skeptic of the permanence of the cure.

**Treatment.** Every effort should be directed toward improving the physical condition and freeing the child from social and educational pressures and frustrations. Specific treatment should be entrusted to the psychiatrist as soon as possible.

MILTON J. E. SENN

# The Endocrine System

## DISORDERS OF THE PITUITARY GLAND

The pituitary gland consists of an anterior lobe and a posterior lobe. In man the pars intermedia, which can be recognized in the fetus, loses its distinction after birth. The anterior lobe develops from the ectoderm of the stomodeum (Rathke's pouch); fetal rests of the original connection of Rathke's pouch with the primitive oral cavity may persist in postnatal life as a craniopharyngeal duct. Sometimes tumors develop from the remnants of this duct (craniopharyngiomas) and give rise to symptoms of glandular and hypothalamic disturbances (p. 1086). The posterior lobe is derived from the infundibulum of the diencephalon and remains histologically and functionally distinct from the anterior lobe.

**Function. Anterior lobe.** Six well defined hormones are produced by the anterior pituitary, and other less well defined substances have been isolated. It is generally agreed that the chromophobe cells do not produce any hormones, that growth hormone is produced by the eosinophilic cells and the follicle-stimulating hormone (FSH) by the basophilic ones. Although not conclusively proved, it is believed that the eosinophilic cells are the source of the luteinizing or interstitial cell-stimulating hormone (LH or ICSH) and of lactogenic hormones and that the basophilic cells produce thyrotropic (TSH) and adrenocorticotrophic hormone (ACTH). This concept is probably too definitive. The pituitary hormones act either directly on the body cells or on other endocrine glands to affect almost every organ. The pituitary gland itself is under the control of the hypothalamus and is reciprocally affected by the hormones produced by other endocrine glands.

The *growth hormone* is believed to act directly upon the body cells and not through other endocrine glands. It is a protoplasmic anabolic agent which promotes growth, but not development or maturation. An excess

results in gigantism or acromegaly; deficiency, in dwarfism. The active principle is a protein substance effective only when administered parenterally. Crystalline growth hormone preparations have been isolated which cause linear growth, weight gain and nitrogen retention in rats and dogs. However, these same preparations have proved remarkably ineffective in human beings. This is due to a unique species specificity of growth hormone; whereas growth hormone prepared from the beef pituitary fails to induce growth or nitrogen retention in man and monkeys, growth hormone prepared from monkey and human pituitaries is effective in man. Only small amounts of human and monkey growth hormones are available for investigative purposes. There are at present no satisfactory methods for assaying circulating growth hormone in children.

The *gonadotropic hormone* can be divided into two fractions. The follicle-stimulating hormone (FSH) is gametokinetic and stimulates growth of the ova in the female and of the germ cells in the male. The interstitial cell-stimulating hormone (ICSH or LH) regulates formation of the corpus luteum in the female and growth of the interstitial tissue of the testes (Leydig cells) in the male. These hormones are of little significance in girls before the age of ten years or in boys before the age of twelve years. At that time gonadotropins begin to appear in the urine and stimulation of the gonads follows.

Urinary gonadotropins are tested biologically, and their values are expressed in mouse or rat units. Various methods are in use. According to one method (Klinefelter and others), the range is 0 to 5 mouse units per day in girls of premenarchal age; 10 to 50 mouse units in mature females; and 100 to 500 mouse units in women after the menopause. Tested by the method of Delfs, normal mature women excrete 10 to 20 rat units in

twenty-four hours. In castrates or in patients with primary hypogonadism the anterior lobe undergoes definite cellular changes accompanied by an overproduction of gonadotropic hormone. The urinary gonadotropins are usually increased in such patients. An excess of estrogens or androgens inhibits the secretion of pituitary gonadotropic hormones.

The *thyrotropic hormone* stimulates the thyroid; an excess may result in hypertrophy and hyperplasia, whereas a deficiency results in inactivity and atrophy of the thyroid gland. A reciprocal relationship exists between the anterior pituitary and the thyroid. Thyroid hormone inhibits production of pituitary thyrotropin, and a low level of circulating thyroid hormone results in accelerated production of thyrotropin. Pituitary thyrotropin is a valuable agent in research and is useful in clinical medicine to differentiate pituitary hypothyroidism from primary thyroid deficiency.

*Adrenocorticotrophic hormone* (ACTH, corticotropin) is the hormone which stimulates the synthesis and release of steroids from the adrenal cortex. It is postulated that the release of corticotropin by the anterior pituitary gland is subject to hypothalamic control. The major hormones liberated by the human adrenal cortex when stimulated by corticotropin are hydrocortisone and corticosterone. There is evidence that androgens, estrogens and progesterone, or precursors of these compounds, are also liberated.

All the actions of corticotropin are mediated by adrenocortical steroids. In the absence of the adrenal cortex no effects are produced by corticotropin. A reciprocal relationship exists between corticotropin and production of adrenocortical hormones. Therefore when an exogenous hormone, such as cortisone, is administered, there is a reduction in corticotropin production. If this administration is prolonged and then suddenly stopped, adrenocortical insufficiency is induced as a result of the pituitary inhibition. The increased corticoid secretion induced by exogenous corticotropin also depresses corticotropin output by the pituitary in a manner similar to that of exogenous cortisone. Therefore adrenocortical insufficiency follows sudden withdrawal of corticotropin therapy. The severity of the adrenal insufficiency depends upon the duration of therapy, the dose used and the rapidity of withdrawal. This adrenal insufficiency is temporary and can be prevented by slowly tapering the dosage and increasing the interval between doses of either corticotropin or cortisone.

**NEOPLASMS.** Tumors of the anterior pituitary may arise from hyperplasia of any of the three principal types of cells. *Chromophobe adenomas* rarely occur in children. They cause symptoms by pressure on adjacent structures, but not by overproduction of a hormone. They may cause pituitary insufficiency by compression of functioning pituitary tissue. An *eosinophilic pituitary adenoma* results in *gigantism* if it occurs before closure of the epiphyses and in *acromegaly* after epiphysial growth of the bones has ceased. These tumors, rare in children, are thought to produce abnormal growth by overproduction of growth hormone. *Basophilic adenomas* may be found in patients with or without *Cushing's syndrome* and are no longer believed to be the cause of this disorder. They do not result in enlargement of the sella, nor do they cause neurologic symptoms in children. Pituitary tumors have never been reported as a cause of precocious puberty.

**Posterior lobe.** The posterior lobe of the pituitary is part of a functional unit known as the neurohypophysis, which consists of (1) the neurons of the supraoptic and paraventricular nuclei of the hypothalamus; (2) their axons, which form the pituitary stalk; and (3) the posterior lobe of the pituitary. Extracts of the neurohypophysis exhibit antidiuretic and oxytocic activities. These hormones, produced by a process of neurosecretion in the hypothalamic nuclei, are transported along the axons down the pituitary stalk and stored in the posterior pituitary or secreted directly into the blood.

The chemical structures of the oxytocic and antidiuretic hormones have been determined by du Vigneaud, who in 1953 synthesized oxytocin. The most clear-cut example of neurohypophysial deficiency is diabetes insipidus. The closer the lesion is to the hypothalamic nuclei, the more complete is the deficiency of antidiuretic hormone. More than 85 per cent of the hypothalamic-hypophysial tracts must be severed before clinical diabetes insipidus becomes manifest. Removal of only the posterior lobe of the pituitary rarely results in diabetes insipidus. Diabetes insipidus will not develop in the absence of the anterior pituitary.

## PITUITARY DWARFISM

**Etiology.** *Pituitary dwarfism without demonstrable lesion of the pituitary (Lévil-Lorain type).* It is presumed that this condition is caused by an absence or inadequate

secretion of growth hormone. Since many of these patients also have delayed puberty, inadequate secretion of gonadotropic hormones is also present. The evidence for growth hormone deficiency is inferential, since there is no assay method sufficiently sensitive to demonstrate variations of its serum levels. Thyrotropic and adrenocorticotrophic activity is usually normal as demonstrated by normal thyroid and adrenal function.

Hereditary pituitary dwarfism has been thoroughly studied in the dwarf silver mouse, in which the condition is recessive. The symptoms and the pathogenesis of the disorder in dwarf mice resemble pituitary dwarfism in man in many respects. The pituitary glands show absence of eosinophilic cells, indicating lack of growth hormone production. Administration of anterior pituitary suspension induces growth and gonadal maturation.

**Pituitary dwarfism resulting from organic lesions of the pituitary.** Any lesion destroying the anterior pituitary causes cessation of growth. Destructive lesions are not selective, and evidence of multiple pituitary hormonal deficiencies will be present. At puberty secondary sex characteristics do not always develop. Deficiency of thyrotropic and adrenocorticotrophic hormones may be clinically apparent or be detected only by appropriate tests of thyroid and adrenal function.

The most common lesion responsible for this type of dwarfism in childhood is the craniopharyngioma. The growth failure almost always antedates the neurologic signs and symptoms associated with this tumor. In rare instances tuberculosis, syphilis, xanthomatous lesions (Hand-Schüller-Christian disease), toxoplasmosis or various tumors are the cause of pituitary destruction. These lesions are frequently associated with detectable roentgenographic changes. Enlargement of the sella or deformation or destruction of the clinoid processes usually indicates a tumor. When intrasellar or suprasellar calcifications are seen, the lesion is almost always a craniopharyngioma.

**Clinical Manifestations.** Pituitary dwarfs are usually of normal size and weight at birth. The retardation of growth is noticed within the first few years of life. There may be a regular but slow growth in height with the increments always below those of the coevals, or periods of lack of growth may alternate with short spurts of growth. Delayed closure of the epiphyses permits growth beyond the time when normal persons cease to grow.

The head is round, and the face short and

broad. The frontal bone is prominent and the bridge of the nose depressed and saddle-shaped. The nose is small, and the nasolabial folds are well developed. The eyes are somewhat bulging. The mandible and the chin are underdeveloped and infantile, and the teeth, which erupt late, are frequently crowded. The neck is short and the larynx small. The voice is high-pitched and remains high after the age of puberty. The genitals are usually undeveloped, but dwarfs have been described whose genitals functioned normally. The extremities are well proportioned, the hands and feet being small (acromicria). Aseptic necrosis of bones (Perthes' disease, Kohler's disease, and the like) is not rare. The skin is often wrinkled and lies in folds, particularly in the face (geroderma). Facial, axillary and pubic hair is usually absent; the hair of the scalp is fine. Sexual maturation may be delayed or absent. Hypoglycemic attacks may occur, and there may be failure of the usual glycemic response following insulin-induced hypoglycemia.

The intelligence of pituitary dwarfs is usually normal. Their physical peculiarities influence their emotions and behavior as they grow older, and they may become shy and retiring.

**Roentgenographic examination.** The fontanelles remain open beyond the second year; in the occipital suture wormian bones may be found. The bones of the vault are thin, and osteoporosis may be noticed. The long bones are slender and poor in minerals. The centers of ossification appear late, and the epiphysal clefts remain open.

The sella turcica is often small, a finding to be expected in a dwarf. There is great variation in the size of the sella in normal persons, and the evaluation of a small sella is difficult. A suprasellar osseous bridge cannot be considered pathologic, since it is seen in about 10 per cent of roentgenograms of the skull.

**Primordial dwarfism.** This type of dwarf is small at birth and remains smaller than persons of the same age throughout life. Aside from retardation of growth, the development is entirely normal. Dentition, ossification and sexual maturation occur approximately at the same time as in taller persons of the same age. Such dwarfs can reproduce. It has been assumed that primordial dwarfs lack only pituitary growth hormone. Primordial dwarfism can be hereditary and be transmitted as a recessive trait. In this case the dwarf is homozygous; if two persons of this type mate, all their children will be homo-

zygous dwarfs. This dwarf mutation could thus give rise to a pigmy race.

**Differential Diagnosis.** It is almost impossible to establish the diagnosis of pituitary dwarfism without a demonstrable pituitary lesion in the prepuberal years. Only with the passing of years and the elimination of other causes for dwarfism may one feel secure with such a diagnosis. It is of great importance to rule out the presence of a destructive intracranial lesion. A history of nausea, vomiting, loss of vision, headaches and increase of the circumference of the head suggests increased intracranial pressure. The eyegrounds must be carefully examined, and roentgenograms may be helpful in localization of a tumor.

Obesity suggests involvement of the hypothalamus, but does not prove the presence of a tumor. Associated hypothyroidism and adrenal insufficiency are indicative of a pituitary lesion, but are rarely present without demonstrable lesions of the pituitary.

Both types of pituitary dwarfs show sexual underdevelopment after the time when puberty should have occurred. The gonads remain underdeveloped because there is no stimulation from the pituitary. Dwarfism resulting from the chondrodystrophies, osteogenesis imperfecta, pseudohypoparathyroidism or the various types of rickets can be recognized by features characteristic of each of them. When retardation in growth is due to cardiac, renal, hepatic or intestinal disease, the cause can be identified by the diagnosis of the underlying disorder.

In girls, gonadal dysgenesis must always be considered. When associated with the usual characteristic congenital deformities, the diagnosis is not difficult. About 80 per cent of these patients are genetically male (male sex chromatin pattern), and after puberty they show high levels of gonadotropin secretion. The osseous development of pituitary dwarfs is definitely retarded, whereas girls with gonadal dysgenesis have only a slight delay of epiphysial development.

**Prognosis.** The prognosis for life depends upon the etiologic factor. If dwarfism is caused by absence of growth hormone without a demonstrable anatomic lesion, the affected person may reach old age. A tumor in the pituitary region may endanger the patient's life. If syphilitic, tuberculous or xanthomatous changes result in pituitary dwarfism, the disease process determines the fate of the patient.

Prognosis for growth is difficult, since an increase in height is possible long after the

age of adolescence because of the persistence of open epiphysial clefts. Sexual maturation may also take place ten or twenty years later than in normal persons.

**Treatment.** Treatment of patients with demonstrable organic lesions should be directed to the underlying disease process. In instances of pituitary dwarfism due to craniopharyngioma acceleration of growth may occur after surgical treatment of the tumor.

There are many contradictory reports concerning treatment with injections of crude pituitary extracts. Since spontaneous growth is possible at any age, reports of the effects of treatment are difficult to evaluate. Difficulty in establishing the diagnosis of pituitary dwarfism increases the uncertainty in evaluating published reports.

In contrast to the ineffectiveness of growth hormone prepared from beef and porcine pituitary glands to stimulate growth in the human dwarf, growth hormone prepared from human and monkey pituitary glands is very effective. Monkey and human growth hormone preparations are available only in small quantities for investigative purposes.

The protein anabolic action of testosterone and related compounds has been used to induce growth. These substances result in a strikingly increased rate of growth of the dwarf. However, the ultimate height attained is almost always subnormal. This is ascribed to accelerated osseous maturation and early closure of epiphysial lines precluding further growth. It has been shown that with the use of methyltestosterone osseous age usually advances more rapidly than height age. Testosterone and related androgens should not be used in slowly growing children, but should be limited to selected instances of severely stunted growth.

## PROGERIA

(PREMATURE SENILITY, HUTCHINSON-GILFORD SYNDROME)

Progeria is a type of dwarfism combined with premature senility. Twenty-nine typical cases have been reported since Hutchinson first described the syndrome in 1886, although many atypical ones have been recorded.

These children appear normal at birth, and their birth weight is usually within normal limits. The weight increases adequately during the first year of life, only to remain almost stationary during the remainder of the first decade, and may eventually reach that of a two- or three-year-old child during the

second decade. The height increases slowly and may not exceed that of an average four- or five-year-old child during the first decade before growth stops completely. The appearance is characteristic and has been described as that of premature old age and of a "plucked bird." The head appears large and is prematurely bald, and the eyebrows are usually absent. The eyes appear prominent, and the nose is "beaked"; the face is small in comparison with the skull, and the chin recedes. The chest is narrow, and the abdomen protrudes. The skin is atrophic, and brown pigmentations are common. The outstanding feature is the absence of subcutaneous fat in the face, on the chest and in the extremities. The veins are prominent; the nails show trophic changes, or they may be absent.

There are no characteristic changes in the blood. Amino-aciduria has been reported in one instance. Abnormally high levels of serum lipoprotein have also been reported. Roentgenograms show thinning and some decalcification of the long bones, shortening of the clavicles, coxa valga, a poorly developed mandible with crowding of the teeth and delay in primary dentition. The intelligence is not affected. Arteriosclerosis may occur as early as five years of age. Arthritis with enlargement of the joints and limitation of motion is common in older patients and has been reported in children as young as six years of age. Anginal attacks and hemiplegia have been reported in the first decade, and the most common cause of death is coronary occlusion. The average age at death is sixteen years.

The *etiology* is obscure. Metabolic studies on one patient by Talbot showed an excessive utilization of calories for energy metabolism. This hypermetabolism was not due to hyperthyroidism.

No treatment has proved effective.

## SIMMONDS' DISEASE

### (PANHYPOPITUITARISM)

Simmonds' disease, or severe pituitary insufficiency, is extremely rare in children. Pathologically, the essential finding is a complete or almost complete destruction of the pituitary gland. The etiology of the destructive lesion may be extremely varied and include tuberculosis, nonspecific granulomas, cysts and tumors; in children, tumors, especially craniopharyngiomas, are the most common finding.

Atrophy of the adrenal cortex, thyroid and gonads and cessation of growth resulting from

the pituitary lesion account for the variety of signs and symptoms. The chief clinical features are failure of growth, loss of weight, asthenia, hypothermia, hypotension, increased sensitivity to cold, mental torpor and absence of sweating. Sexual maturation fails to take place or regresses if already present. Thus there may be atrophy of the gonads and genital tract with amenorrhea and loss of pubic and axillary hair. There is a tendency to hypoglycemia and coma. Laboratory studies show a low protein-bound iodine level and diminished radio-iodine uptake, low levels of serum and urinary corticosteroids, hypoglycemia and anemia. There is an increase in serum level of corticosteroid following administration of corticotropin, and of protein-bound iodine and of radio-iodine uptake after injection of thyrotropin.

If the lesion is an expanding tumor, symptoms such as impaired vision, ocular disturbances, pathologic sleep, mental retardation and other neurologic signs may be present. Changes in or around the sella may be present.

In the differential diagnosis cachexia resulting from tuberculosis, malignancy, hyperthyroidism, malnutrition and anorexia nervosa should be considered. *Addison's disease* may present a clinical picture resembling that of Simmonds' disease, but pigmentation is slight or absent in Simmonds' disease. In *progeria* there is no evidence of reduced pituitary function.

*Treatment* should be directed against the primary disorder. If a tumor is present, surgical treatment must be considered. The secondary deficiencies of the adrenal and thyroid glands can be relieved by substitution therapy. The adrenocortical insufficiency should be treated before thyroid therapy is started, and in all cases the initial dose of thyroid should be small to prevent changing a relative hypoadrenalism into an absolute one.

## PITUITARY GIGANTISM AND

### ACROMEGALY

Certain forms of gigantism and acromegaly are associated with hyperplasia or tumors of the eosinophilic cells of the anterior pituitary gland. It is assumed that hyperfunction of the eosinophilic cells of the adenohypophysis results in increased production of growth hormone. In young persons with open epiphyseal clefts overproduction of growth hormone results in gigantism, while in patients with closed epiphyses acromegaly develops.

**Pituitary gigantism** is rare, since eosinophilic adenomas seldom occur in childhood. In most of the cases recorded the abnormal growth started at the time of puberty, and the abnormal height was attained within the next few years. Such giants may grow to a height of 8 feet and more. After closure of the epiphyses acromegaly may be superimposed upon gigantism. The *prognosis* for life is poor, since the adenoma may cause increased intracranial pressure or may undergo cystic degeneration followed by signs of pituitary deficiency.

In the *differential diagnosis* hereditary tall stature must be considered. In this condition there is usually abnormal height in one or both parents or in close relatives. Such tall persons are well proportioned and free of signs of increased intracranial pressure. The abnormal growth seen in the period of preadolescence in obese children represents a temporary state; though such children may become tall, they do not attain the height of giants. Children with precocious puberty are often unusually tall, but do not develop into giants, since their epiphyses close early and growth ceases prematurely.

**Acromegaly** is rare in children, but transitory acromegalic features are sometimes observed in adolescents. Acromegaly consists chiefly in an enlargement of the distal parts of the body, but the manifestations of abnormal growth actually involve all parts of the body. The circumference of the skull increases, the nose becomes broad, and the tongue is often so enlarged that it protrudes between the thick lips. The mandible grows, and the teeth separate. The fingers and toes grow chiefly in thickness. There is frequently a dorsal kyphosis. The skin and the mucous membranes are thickened, and the voice becomes deep. There may be enlargement of the internal organs, but the testes or ovaries become atrophic as the disease progresses. The basal metabolic rate is high in the early stage of the disease, but decreases later. Polydipsia, polyuria and glycosuria are not rare, and the glucose tolerance curve may be of the diabetic type. Fatigue and lassitude are early symptoms; signs of increased intracranial pressure appear late. Roentgenograms reveal enlargement of the sella turcica. An elevated serum phosphorus may be present.

The course is usually protracted; in rare cases pituitary insufficiency develops early.

*Treatment* depends upon the symptoms. If signs of increased intracranial pressure are

present, surgical intervention is indicated. In some cases acromegaly and headaches are improved by roentgen treatment of the pituitary gland. Large doses of estrogen have been effective in decreasing the rate of growth, perhaps by inhibiting production of growth hormone. There is no satisfactory treatment for hereditary tall stature and gigantism.

## DIABETES INSIPIDUS

Diabetes insipidus is the result of pathologic changes involving any part of the close functional unit made up of the posterior lobe of the pituitary, the supraoptic and paraventricular nuclei of the hypothalamus and the hypothalamico-hypophysial fibers. Such changes result in deficiency of the antidiuretic hormone, which acts directly on the distal tubules and collecting ducts to facilitate reabsorption of water. This disorder is, therefore, characterized by inability of the kidney to produce a concentrated urine. When antidiuretic hormone is administered, there is a remarkable decrease in the amount of urine excreted and an increase in its specific gravity. Physiologic doses of Pitressin do not influence renal solute output either quantitatively or qualitatively.

**Etiology.** Diabetes insipidus may occur as a hereditary disorder; transmission is usually as a simple dominant character or as a dominant with incomplete penetrance in the female. The largest family studied showed thirty-five affected individuals in a family of 220 members in five generations. The histopathologic changes in the hereditary form are not known.

Any lesion damaging the neurohypophysis or hypothalamus may result in diabetes insipidus. In the case of a tumor, symptoms of increased intracranial pressure may accompany, or they may follow years later, the symptoms of diabetes insipidus. Injuries of the head, such as basal skull fractures, may lead to diabetes insipidus immediately, or symptoms may appear after several months. In xanthomatosis (Hand-Schüller-Christian syndrome) the disturbance of water metabolism may be accompanied by exophthalmos and defective areas in the skull. Encephalitis, tuberculosis, leukemia, actinomycosis and congenital syphilis may occasionally cause diabetes insipidus.

In many instances no specific etiology can be determined. The search for a lesion should be continued indefinitely, since diabetes in-

insipidus may be the first recognizable sign of an intracranial tumor and antedate neurologic signs by years.

**Clinical Manifestations.** Polydipsia and polyuria are the outstanding symptoms of diabetes insipidus. In families with the hereditary disorder the polyuria is noted in early infancy. The infant cries excessively and will be dissatisfied when additional milk is offered, but is quieted by water. Hyperthermia, rapid loss of weight and collapse are common in infancy. Vomiting, constipation and growth failure may be observed. Dehydration in early infancy may result in brain damage and mental deficiency.

In a child who has acquired bladder control, enuresis may be the first symptom. The excessive thirst is a disturbing symptom and interferes with play, learning and sleep. Children with diabetes insipidus do not perspire, and their skin is dry and pale. Anorexia is a common symptom; there is a preference for carbohydrates.

The urine is pale or colorless, and the specific gravity varies from 1.001 to 1.005 and does not exceed 1.007 except during febrile episodes; the urine is hypotonic to the blood. Four to 10 liters of urine and more may be eliminated daily. Glomerular filtration and tubular excretory rates are within normal limits.

Other signs and symptoms depend on the primary lesion; thus patients with xanthomatosis may show areas of rarefaction in roentgenograms of the skull or other bones. Lesions initially causing diabetes insipidus may progress and eventually destroy the anterior pituitary. In such instances the symptoms of diabetes insipidus tend to ameliorate or disappear completely.

**Differential Diagnosis.** Primary polydipsia, a symptom occurring in psychopathic patients, can be recognized by a concentration test, since such persons are able to produce a concentrated urine. In chronic nephritis the nonprotein nitrogenous constituents of the blood and the renal function tests are abnormal. Nephrogenic diabetes insipidus can be recognized by the failure of response to Pitressin. After the diagnosis of diabetes insipidus has been established the underlying process must be determined.

**Prognosis.** The prognosis depends upon the underlying condition. It is favorable in the hereditary type and less so in cases resulting from syphilis and encephalitis. If the disorder follows trauma, spontaneous cure may occur. The prognosis of patients with a brain tumor

or xanthomatosis depends upon the site of the lesions, and with neoplasms upon the type of cell.

**Treatment.** The etiologic factor deserves first consideration in the treatment. Tumors will require surgical intervention in the majority of instances. Specific treatment is indicated in syphilis. Roentgen ray treatment is recommended in the management of the Hand-Schüller-Christian syndrome.

If the underlying condition is unknown or not amenable to therapy, symptomatic treatment with Pitressin is useful. Aqueous Pitressin is given in doses of 1 to 3 cc. per day, usually divided into two or three injections. Polyuria and polydipsia are diminished in the majority of instances, and the patient is relieved of these disturbing symptoms. This treatment is sometimes complicated by intestinal cramps, nausea, colic or pallor, which appears within fifteen to thirty minutes after injection. Pitressin tannate in oil, 0.2 to 1 cc., administered intramuscularly every one to three days as determined for the individual patient is the treatment of choice. Pitressin may also be administered intranasally, thus avoiding repeated injections. Cotton pledgets moistened with the aqueous solution may be placed in the nostrils and allowed to remain for three to five minutes, two or three times a day; or the dry powder can be placed in the nose with the finger. This therapy may cause nasal irritation, and occasionally allergy has developed in both children and their mothers.

#### PITRESSIN-RESISTANT DIABETES INSIPIDUS

(NEPHROGENIC DIABETES INSIPIDUS, "WATER-BABIES")

This is a renal tubular disorder occurring nearly always in boys and probably transmitted as a sex-linked recessive character. These patients have a normal production of antidiuretic hormone but a failure of end-organ response in the renal tubule.

The onset is shortly after birth, the symptoms being those of diabetes insipidus. In addition to polyuria and polydipsia, unexplained fever, vomiting, constipation and failure to thrive are common. Fluid restriction or elevated environmental temperature may result in rapid loss of weight and peripheral collapse. Growth is retarded, and mental development may be impaired.

Hyperelectrolytemia and azotemia are almost constant findings in early infancy, but tend to subside later in life. The urine has a

low specific gravity, which may rise to about 1.010 during severe dehydration. Administration of hypertonic saline solution or Pitressin fails to induce antidiuresis and has no effect on the volume or specific gravity of urine.

Treatment consists in administration of water at frequent intervals in amounts sufficient to prevent dehydration and fever. Hyper-electrolytemia is thought to be an important factor in causing mental retardation. It may be almost impossible to maintain normal serum electrolyte levels without giving a low protein diet, which is justifiable in early life, even if growth is retarded. When sufficient water is taken, the protein in the diet may be increased to usual levels.

PRECOCIOUS PUBERTY

Although the average age of children at the onset of puberty in the United States is eleven to twelve years in girls and twelve to thirteen years in boys, there are wide ranges of individual variation. Puberty may be delayed to eighteen to twenty years of age or may take place much earlier than usual. The following physical changes are recognized as evidence of abnormally early sexual development: (1) breast enlargement before eight years of age; (2) menarche before ten years; (3) pubic or axillary hair before nine years, especially if dark and coarse; (4) enlargement of the clitoris or penis disproportionate to the age of the child; and (5) other associated phenomena at a disproportionate age such as facial hair, acne, change in voice, pigmented areolas of the nipples and pigmentation of the sexual organs.

The normal physiologic mechanism which initiates the onset of puberty is not known. At puberty there is a release of gonadotropic hormones from the anterior pituitary which stimulate the Leydig cells of the testes to secrete testosterone and the follicles of the ovary to secrete estradiol. At the same time androgen production by the adrenal cortex increases. This latter event has been called the 'adrenarche' by Albright. The steroid hormones released then act on the various end organs to produce the secondary sex characteristics. There is evidence that this series of events is initiated by the hypothalamus, which sends neurohumeral stimuli to the anterior pituitary.

Precocious puberal development may be divided into true precocious puberty and precocious pseudopuberty. True precocious puberty is always isosexual and indicates not

Table 114. Conditions Causing Precocious Puberty\*

only precocity of the secondary sexual characteristics, but also an increase in the size of the gonads with production of mature sperm or ova. In precocious pseudopuberty only the secondary sex characteristics appear; the gonads do not mature, and there is no spermatogenesis or ovulation. In pseudopuberty the precociously appearing sex characteristics may be isosexual or heterosexual. This latter group will be discussed in the chapters on the Adrenogenital Syndrome (p. 1186) and on the Primary Lesions of the Ovary (p. 1201) and of the Testis (p. 1197).

TRUE PRECOCIOUS PUBERTY

PRECOCIOUS PUBERTY WITHOUT OTHER PATHOLOGIC FINDINGS (CONSTITUTIONAL)

No etiologic factor can be found and the early onset of puberty is considered a physiologic process which begins at an unusually early age. It is estimated that 90 per cent of the cases of true sexual precocity are of this type and occur much more commonly in girls than in boys.

In girls there is precocious development of the breasts and of the external and internal genitals, premature appearance of axillary and pubic hair and precocious menstruation. These changes are usually associated with a moderate advancement of physical growth,

FIG. 335. Constitutional precocious puberty. Patient at (A) 3-11/12 and (B) at 5-8/12 years of age. Breast development and vaginal bleeding began at 2½ years of age. Osseous age was 7½ years at 3-11/12 and 13 years at 6-11/12 years of age. Repeated estrogen assays have varied between 12 and 132 mouse units. Gonadotropic hormone has never been demonstrated in the urine. 17-Ketosteroids have varied between 1.6 and 2.1 mg. per 24 hours. Intelligence and dental age are normal for chronologic age.

height, weight and ossification. The increased rate of skeletal growth in both boys and girls may result in earlier than usual closure of the epiphyses, so that ultimate stature may be somewhat less than it would have been otherwise. Dental age and mental development, however, are usually compatible with chronologic age. Menarche has been observed as early as seven months of age, but usually occurs after four or five years. Corpora lutea are present. The early cycles are frequently anovulatory, and, as in normal puberty, menstruation may not have a normal rhythm in the beginning. Pregnancy has been reported in this type of precocity as early as five and one-half years of age.

In boys secondary sex characteristics as well as spermatogenesis have been observed at the age of five or six years. Testicular biopsies in such cases have shown all elements

of the testes to be stimulated. If the precocity is complete, various degrees of spermatogenesis are present, but, even if incomplete, the interstitial cells make their appearance. In pseudoprecocity the interstitial cells do not develop, and spermatogenesis does not occur. Constitutional precocious somatic and sexual development in males occasionally occurs as a familial trait transmitted by a dominant gene.

The urinary excretion of gonadotropic hormones, estrogens and 17-ketosteroids may correspond to that of normal mature women or men. Gonadotropins are frequently not demonstrable in the urine of children with true precocious puberty, although pituitary release must unquestionably occur. Cornification of the vaginal epithelium can be demonstrated on stained vaginal smears.

In the *differential diagnosis* lesions of the

central nervous system, the adrenogenital syndrome, granulosa cell tumors of the ovaries, Leydig cell tumors and medicational pseudo-precocity must be considered. A carefully obtained history and physical examination in addition to appropriate laboratory studies are indicated, and a pelvic examination under anesthesia may be necessary to determine whether there is an ovarian tumor.

*Treatment* consists essentially in psychologic management of the patient and family. A detailed explanation to the parents with reassurance of the harmlessness of the condition is imperative. They should also be told that the precocious manifestations will persist, but that by the age of ten to fourteen years the child will not be different from other children. Such children should also be guarded against abuses that could result in pregnancy. The few data available indicate that these patients have a normal reproductive span and that menopause takes place within the usual time.

#### PRECOCIOUS PUBERTY WITH POLYOSTOTIC FIBROUS DYSPLASIA AND ABNORMAL PIGMENTATION

See also page 1246.

When these bony lesions are associated with patchy cutaneous pigmentation and endocrine dysfunction, the clinical combination is frequently referred to as *McCune-Albright's syndrome*. The most common endocrine disturbance is sexual precocity, which occurs principally in the female. The pathogenesis is not known, but the disease is thought to be the result of a congenital disorder of development involving the skeleton, the skin and the hypothalamus.

Vaginal bleeding has been reported as early as four months of age and secondary sex characteristics at six months, but the average age at menarche is three years. Advanced ossification is a frequent finding and is common to both sexes. Thyroid enlargement with or without hyperthyroidism, gynecomastia and acromegalic features have occasionally been observed.

The symptoms of precocity, the demonstrable hormonal deviations and the treatment are the same as those described for constitutional precocious puberty. Serum calcium and phosphorus levels are normal. Alkaline phosphatase is normal or increased. Prognosis is favorable for longevity, but deformities may result from the bony lesions and repeated pathologic fractures. The disease becomes stationary in adult life.

FIG. 336. Precocious puberty associated with polyostotic fibrous dysplasia (McCune-Albright syndrome) in a girl 6 years of age; at this time she weighed 46 pounds and was 43 inches in height. Note the areas of dermal pigmentation. Roentgenograms revealed osseous lesions in the femurs and pelvic bones and questionable ones in the vertebrae. Menarche was at 3½ years of age. (Courtesy of Dr. Ralph V. Platou.)

#### PRECOCIOUS PUBERTY RESULTING FROM ORGANIC BRAIN LESIONS

A wide variety of lesions of the central nervous system may be associated with precocious puberty. These lesions have in common involvement of the hypothalamus by invasion, direct contiguity or pressure mediated by occlusion of the ventricular system with dilatation of the third ventricle. Thus tumors, hamartomas, postencephalitic scars, tuberculous meningoencephalitis and hydrocephalus have been associated with precocity.

Tumors of the pineal body are a rare cause of precocious puberty. These lesions, as in all instances of sexual precocity secondary to lesions of the central nervous system, are more frequent in boys than in girls. The reason for this is unknown. It is generally agreed that precocity associated with a pineal tumor is due either to involvement of the posterior hypothalamus or to pressure exerted on the aqueduct of Sylvius and posterior hypothalamus. The pineal body has no known endocrine function. Because some of the non-endocrine symptoms associated with pineal tumors are rather characteristic, they have

A

B

FIG. 337. Precocious puberty in a boy which was induced by a lesion of the floor of the third ventricle involving the suprasellar region. Age at the time of picture A was  $2\frac{1}{2}$  years. Weight and measurements were those of a child 4 years of age. Anterior fontanel did not close until 27 months of age. Began to have polyuria and polydipsia at one year of age. Penis began to enlarge at the age of about 2 years. Had a deep voice. Eyegrounds were normal. Roentgenogram of the skull showed intracranial calcifications. At 9 years of age had no failure of vision; was mentally backward; was overweight and overheight for age; had pubic and axillary hair. At 11 years of age (B) growth had ceased for about 2 years; secondary sexual characteristics were overdeveloped, but apparently there was no libido. Epiphysial closure was advanced, the calcified masses were still visible on the roentgenogram, eyegrounds were normal, polyuria and polydipsia were present, but not marked, and there was mental retardation. (Courtesy of Dr. Stewart Matthews, Wyoming, Ohio.)

been referred to as the pineal syndrome (*Pellizzi's syndrome*).

Central nervous system lesions always cause isosexual true precocity. It is believed that these lesions produce their effect through the intact anterior pituitary gland. The lesions either stimulate the anterior lobe or interfere with a mechanism which normally inhibits gonadotropic release in children before puberty. Pituitary tumors have never been shown to cause precocious sexual development.

The endocrine pattern of hypothalamic lesions is identical with that observed in true precocious puberty without demonstrable organic lesions. Precocious puberty of this type

may precede by several years the onset of signs of increased intracranial pressure. Thus a child who is considered initially to have precocious puberty without a lesion may eventually be found to have a hypothalamic tumor. Some of these lesions, such as the hamartomas, may grow slowly and cause few signs of increased intracranial pressure. Other hypothalamic signs or symptoms such as diabetes insipidus, hyperthermia, obesity, unnatural crying or laughing may suggest the diagnosis. A history of convulsions, retarded mental development or other neurologic signs should also make one suspect a lesion of the central nervous system.

Roentgenographic examination of the skull

and electroencephalographic studies, although rarely of value, are essential parts of the examination, and on occasion pneumoencephalography or ventriculography is indicated.

*Treatment* depends on the lesion. Surgical decompression followed by roentgen therapy is usually indicated when removal of a tumor is not possible.

#### INCOMPLETE (PARTIAL) PRECOCIOUS DEVELOPMENT

Individual manifestations of puberty without the complete picture of precocious development are occasionally encountered; development of the breasts and growth of sexual hair are the two most common ones.

#### SIMPLE HYPERTROPHY OF THE BREASTS

Precocious enlargement of the breasts may occur without any other secondary sex change. Enlargement of the breasts may represent the first sign of true or pseudoprecocious puberty or may merely represent a harmless abnormality. Thorough diagnostic study and a prolonged period of observation are indicated in all instances. Occasionally the hypertrophy of the breasts disappears spontaneously. It has been suggested that the mammary gland may be unusually sensitive to small amounts of estrogens secreted by the ovaries, whereas

FIG. 338. Simple hypertrophy of the breasts in 3-month-old girl. No demonstrable urinary estrogens or gonadotropin. Normal growth and genitals. Note the disparity in size of the two breasts. This is common finding in this condition as well as in normal puberty.

other structures, being normally responsive, do not react until greater amounts are produced at puberty. The usual tests for urinary estrogens are not sensitive enough to detect their presence. There is no cornification of the vaginal epithelium, and gonadotropins and 17-ketosteroids are normally present in the urine only in small amounts.

#### PREMATURE DEVELOPMENT OF SEXUAL HAIR

The appearance of sexual hair at an early age without any other evidence of maturation has been termed "premature pubarche" and is considered a harmless variation of precocious adolescence. It is much more frequent in girls than in boys. Hair appears first on the labia majora, later in the pubic region and finally in the axilla. Most of these children are taller than average, and the bone age is generally one to four years in advance of the chronological age. There is no evidence of true virilization. In our experience this disorder has been most common in mentally defective girls. Wilkins suggests that this variation in pattern of sexual development may be due either to an increased sensitivity of sexual hair follicles to normal levels of androgens present during the preadolescent period or to premature increase in secretion of adrenal androgens before the pituitary gonadotropic mechanism becomes activated. The 17-ketosteroids are not increased beyond values normal for the age. This condition must be differentiated from early true precocious puberty, adrenal cortical tumors and adrenal hyperplasia. Parents need to be assured that this condition is a harmless variation of development.

#### MEDICATIONAL PRECOCITY

Although this is a type of pseudopuberty, it is included here to emphasize the fact that a variety of medicaments can induce the appearance of secondary sexual characteristics which may be confused with true precocious puberty. A careful history to exclude accidental exposure to or ingestion of sex hormones is of paramount importance. Precocious pseudopuberty in girls accidentally ingesting stilbestrol has been reported. Exogenous estrogens may induce an intense, dark brown color to the areola of the breasts which is not usually seen in endogenous types of precocity. The precocious changes disappear after cessation of administration of the exogenous hormones.

**Table 115. Comparison of Fröhlich's Syndrome, Obesity of Adolescence and Laurence-Moon-Biedl Syndrome**

	<i>Fröhlich's Syndrome</i>	<i>Obesity of Adolescence</i>	<i>Laurence-Moon-Biedl Syndrome</i>
Onset of symptoms.....	Any age	About 8 years	Birth
Obesity.....	Moderate	Moderate to excessive	Marked
Genital development.....	Delayed	Boys: slow Girls: normal	Delayed
Development of secondary sex characters.....	Delayed	Boys: slow Girls: normal	Delayed
Skin.....	Dry, scaly	Moist; perspiration increased	Moist
Skeleton.....	Slender	Heavy	Heavy; polydactylism
Headaches; vomiting.....	Present	Absent	Absent
Eye grounds.....	Choked disk or optic atrophy often present	Normal	Retinitis pigmentosa; optic atrophy
Mentality.....	Usually normal	Usually normal	Retarded
Family history.....	Usually negative	Often familial	Often familial

### ADIPOSOGENITAL DYSTROPHY INDUCED BY LESIONS OF THE HYPOTHALAMUS AND OF THE PITUITARY GLAND

#### FRÖHLICH'S SYNDROME

Lesions of the hypothalamus caused by craniopharyngiomas, tumors of the pituitary or other structures adjacent to the hypothalamus, trauma or encephalitis can cause a syndrome of obesity and sexual infantilism. Some of the patients also have diabetes insipidus and retardation of growth. Since obesity may occur in pituitary dwarfs, transitional forms are encountered in which the differential diagnosis between Fröhlich's syndrome and pituitary dwarfism becomes uncertain. It is assumed at present that lesions of this type cause obesity by infringing upon hypothalamic areas, while retardation of sexual development is explained by interference with function of the anterior pituitary. The patient originally described by Fröhlich had a cyst in the region of the pituitary gland which caused headaches, vomiting, loss of vision, destruction of the dorsum sellae, obesity of the trunk, abdomen and genital region, and retardation of sexual development. It is useful to limit the term "Fröhlich's syndrome" to cases which show this group of symptoms.

**Clinical Manifestations.** The obesity is usually moderate in children and affects chiefly the regions of the breast, lower abdomen and genitals. In males the penis may be imbedded in adipose tissue and the testes undescended and small. The face remains beardless and the voice high-pitched after the age of adolescence. These symptoms as well as the fat distribution give such boys a femi-

nine appearance. In females there is accumulation of fat in the mammary region, but the glandular tissue is undeveloped. The external and internal genitals remain undeveloped, and menstruation is delayed or absent. Ossification is delayed in both sexes, and pubic and axillary hair is sparse or absent. The skin is dry and scaly.

It is important to diagnose the presence of a brain tumor (see p. 1084) as early as possible. In differential diagnosis the benign adiposity of adolescence and the Laurence-Moon-Biedl syndrome must be considered. Klinefelter's syndrome (p. 1197), associated with a female sex chromosomal pattern, must also be considered.

**Prognosis and Treatment.** The prognosis is usually unfavorable. Surgical intervention is often indicated if a brain tumor is demonstrated.

## DISORDERS OF THE THYROID GLAND

### GENERAL CONSIDERATIONS

The main function of the thyroid gland is to synthesize thyroxin. Iodine is essential for the production of thyroxin, and it has been estimated that the daily requirement of this element is about 40 to 100 micrograms. Regardless of the chemical form upon ingestion, iodine eventually reaches the thyroid gland as iodide. Thyroid tissue has a special avidity for this element and is able to collect, concentrate and store it for subsequent use.

Before the trapped iodide can be utilized it must be oxidized to its elemental form. This reaction probably occurs within the thyroid cells and is catalyzed by an enzyme which is believed by some to be a peroxidase. The thyroid cells also elaborate the thyroid protein, which is a globulin with tyrosine units. The amino acid tyrosine is iodinated to form diiodotyrosine; two molecules of diiodotyrosine unite to form one molecule of thyroxin. The hormone is then stored in the lumen of the follicle in the colloid until ready

to be delivered to the body cells. The thyroglobulin has a molecular weight of about 675,000 and cannot diffuse through the cell wall of the follicle, but must be split into smaller molecules by proteolytic enzymes before it can diffuse into the capillaries.

Triiodothyronine occurs in appreciable quantities in the normal thyroid. It has also been demonstrated in the serum and in other tissues, but its role is not clear. Triiodothyronine is similar in structure to thyroxine, except that it has three rather than four atoms of iodine. This substance is four to five times as active physiologically as thyroxine and has a much shorter latent period. It provides complete replacement in human hypothyroidism. It is not clear whether triiodothyronine is secreted by the thyroid or is formed in peripheral cells by deiodination of thyroxine.

The thyroid gland is under control of the anterior pituitary, which is, at least in part, under the control of the hypothalamus. In the anterior pituitary the basophilic cells produce the thyroid-stimulating hormone, also known as thyrotropin, or TSH. This hormone stimulates the proteolytic enzymes in the thyroid gland and effects release of the thyroid hormone. An excess of TSH results in hypertrophy and hyperplasia of the thyroid cells, increased collection of iodine and increased synthesis of thyroid hormone. Anterior pituitary production of thyrotropin is inhibited by the thyroid hormone secreted, and thyrotropin production is activated in states of decreased thyroid hormone production. Exogenous thyroid likewise inhibits TSH production, resulting in decreased synthesis of endogenous thyroid hormone.

In the circulation thyroxine becomes bound to a specific fraction of the serum protein. This iodine is known as the protein-bound iodine (PBI); it furnishes an accurate index of the circulating thyroid hormone. The serum level of PBI for euthyroid children or adults is 4 to 8 gammas (micrograms) per 100 ml. At birth the PBI in the infant approximates that of the mother's, with a mean value of 8.3 gammas per 100 ml. This value increases further during the first week of life to reach a mean value of 12 gammas. Then it gradually decreases, but does not reach a mean value as low as that of older children until about one year of age. In hypothyroidism the value is usually considerably below 3 gammas per 100 ml., and in hyperthyroidism it is above 8 gammas. Administration of iodides in large doses to euthyroid persons or the use of radiographic contrast media con-

taining iodine, prior to the determination of the PBI, will result in misleading, elevated values.

The iodine-trapping or concentrating mechanism of the thyroid can be used as a test of thyroid function. Radioactive iodine ( $I^{131}$ ), with a half-life of eight days, is given to the patient orally (usually by gavage to infants). The quantity used is based on the patient's weight; doses as small as 5 microcuries have been adequate in small infants. The radioiodine concentrated in the thyroid gland emits gamma rays, which can be measured by placing a "counter" over the patient's thyroid. The estimate of the uptake is usually made twenty-four hours after the radioiodine has been administered. Normal values vary, depending upon the equipment and technique used, but an uptake of less than 10 per cent usually indicates hypothyroidism. Falsely low values may be due to vomiting of the radioiodine, ingestion of large amounts of iodine either as food or medicine, or administration of exogenous thyroid. Some cases of hypothyroidism are associated with normal or elevated uptakes of radioiodine (p. 1167).

The thyroid hormone increases the metabolic processes of the body by direct action on the cells. It increases basal consumption of oxygen and elimination of carbon dioxide and influences water metabolism. The glucose tolerance is decreased and calcium and phosphorus excretion increased by it. It stimulates the circulation and increases the cardiac rate. Large doses of thyroid lead to myasthenia and increased creatinuria.

There is some evidence that in hypothyroidism the conversion of carotene to vitamin A is disturbed. Patients with hypothyroidism tend to have low vitamin A values and high carotene values in the blood plasma.

Congenital athyreosis in the human subject results in stunting of mental, physical and sexual development. The thyroid, however, is not capable of stimulating growth in the absence of growth hormone, although large doses of growth hormone are capable of stimulating some growth in completely thyroidectomized animals.

The synthesis of hormone by the thyroid is disturbed by certain "antithyroid drugs." The thiocyanate ion prevents concentration of iodide in the gland and causes a discharge of stored iodide. Propylthiouracil and related compounds do not interfere with collection of iodide by the gland, but in some way prevent its fixation in organic combination. These substances interfere with formation of thyroid

hormone, which in turn results in increased production of thyrotropic hormone and enlargement of the thyroid. Thus these compounds are termed goitrogens.

### CONGENITAL HYPOTHYROIDISM

(CONGENITAL APLASIA [HYPOPLASIA] OF THE THYROID GLAND, SPORADIC CRE TINISM)

**Etiology.** In the majority of instances sporadic cretins have either complete absence of the thyroid gland or rudiments which are hypoactive and may be found in the tongue or neck. The factors which interfere with normal embryologic development of the thyroid are not known. In rare instances several members of a family may be born without thyroid glands (*familial cretinism*); such instances must not be mistaken for endemic cretinism. Sporadic cretinism has occurred in one of monozygotic twins at least six times. It therefore appears that unknown intrauterine factors may play a role in its etiology.

Occasionally children living in regions where iodine is abundant and hence in which endemic cretinism is not present, have evidences of hypothyroidism with normally sized or enlarged thyroid glands. They have been found capable of accumulating iodine normally, but are unable to secrete adequate

amounts of hormone. The gland may eventually become goitrous as a result of stimulation with excessive thyrotropin secreted in response to the low level of circulating thyroid hormone. This type of hypothyroidism may occur in more than one sibling, and can be subdivided, depending upon the kind of defect in the synthesis of the hormone. Four different defects have been demonstrated, including those in which some of the glands appear unable to combine iodine with tyrosine and those in which the gland primarily produces iodinated amino acids other than thyroxine which are relatively inactive physiologically.

A selective deficiency of thyrotropin, as a cause of hypothyroidism, has been observed in children with acquired hypothyroidism, but not in congenital hypothyroidism.

**Clinical Manifestations.** Sporadic cretinism is seldom recognized at birth, since the congenital symptoms, such as pallor, constipation, and dryness of the skin, are not sufficiently characteristic to permit the diagnosis. Retardation of osseous development can be shown roentgenographically at birth. Cretins may be significantly heavier at birth than normal newborn infants. Unusual prolongation of physiologic icterus may be the earliest sign, and difficulty in feeding is a common early manifestation. These infants cry little,

FIG. 339. Congenitally hypothyroid infant at 6 months of age. Infant fed poorly in neonatal period and was constipated. Had persistent nasal discharge and large tongue. Very lethargic, no social smile and no head control. A, Note puffy face, dull expression, hirsute forehead. Serum cholesterol 172 mg. per 100 ml., alkaline phosphatase 4.8 Bodansky units, negligible uptake of radio-iodine. Osseous development that of newborn. B, Four months after treatment with U.S.P. thyroid. Note decreased puffiness of face, decreased hirsutism of forehead and alert appearance.

FIG. 340. Epiphyseal dysgenesis in 2 patients. A, Dysgenesis of the epiphyses of the knee in a 7-months-old infant with untreated cretinism indicating prenatal hypothyroidism. B, Dysgenesis of the head of the humerus in an 8½ year old child who had been inadequately treated with thyroid.

sleep much, and have poor appetites. The abdomen is large, and an umbilical hernia is usually present. The temperature is subnormal. The retardation of physical and mental development becomes greater during the following months, and by the end of the first year the clinical picture is fully developed. However, the signs and symptoms may be sufficiently characteristic to permit the diagnosis within the first few weeks of life.

The child is stunted in growth, the extremities being short and the head large. The anterior fontanel is widely open, the eyes are far apart, and the bridge of the broad nose is depressed. The palpebral fissures are narrow and the eyelids swollen. The mouth is kept open, and the thick and broad tongue protrudes from it. Dentition is delayed, and the erupted teeth have a tendency to decay rapidly. The neck is short and thick, and there may be deposits of fat above the clavicles and between the neck and shoulders. The hands are broad and the fingers short. The skin is dry and scaly, and there is little perspiration. Myxedema manifests itself particularly in the skin of the eyelids, of the back of the hands and of the external genitals. Carotenemia may cause a yellow discoloration of the skin, but the scleras remain white. The scalp is thickened, and the hair is coarse, brittle and scanty. The hairline reaches far down on the forehead, which usually appears wrinkled. The skin is cold to the touch. The pulse is slow.

The increasing discrepancy between the chronologic and bone ages can be demonstrated roentgenographically in untreated cases. The epiphyses often show multiple foci of ossification (epiphyseal dysgenesis). Deformity ("beaking") of the twelfth thoracic or first or second lumbar vertebra is also common. The muscles are usually hypotonic. In rare cases a generalized muscular hypertonia has been observed. Such children may have an athletic appearance due to a pseudohypertrophy of the muscles. There is obstinate constipation which usually does not respond to laxatives. Anemia is often present and is refractory to treatment with hematinics.

The mental development of cretins is usually retarded. They appear lethargic and are late in sitting and standing. The voice is coarse, and they do not learn to talk. The degree of physical and mental retardation increases as they become older. Sexual maturation is delayed or does not take place at all.

The basal metabolic rate is decreased. The cholesterol level of the serum is often, but not always, increased; fluctuations are marked. Values of 250 to 600 mg. per 100 ml. of serum are found in children with hypothyroidism, as compared to a range of 100 to 300 mg. in normal children. There is an increase in the cholesterol level of treated children with hypothyroidism six to eight weeks after treatment has been discontinued. In young infants with hypothyroidism the cholesterol level is frequently not elevated,

so that determinations may be of little help in the early recognition of cretinism.

The serum phosphatase is decreased and the carotene level often increased.

The protein-bound iodine (or butanol-extractable iodine) level of the serum is a reliable measurement of thyroid function (p. 1164). In cretins values under 2 gammas per 100 ml. are usually obtained. Uptake of radioactive iodine by the thyroid gland is also a fairly reliable test of thyroid function (p. 1164).

In *goitrous cretinism* (see Etiology) there are all the manifestations of cretinism with supportive laboratory evidence, except a normal or elevated uptake of radioactive iodine. These patients are not iodine-deficient, nor have they been exposed to known goitrogens. Apparently the thyroid gland is capable of accumulating iodine normally, but is unable to convert it into thyroxine. Most of the patients reported to date have shown intense compensatory hypertrophy of the gland with large goiters. Cretinous infants who show a normal or elevated radioactive iodine uptake and thyroids of normal size presumably are too young to show the goitrous enlargements seen in some of the older children because they have not been stimulated long enough with endogenous TSH. The serum protein-bound iodine level may be low, normal or elevated.

When there is only a partial deficiency of the thyroid hormone, the symptoms may be milder, the syndrome incomplete and the onset delayed.

Other malformations are occasionally found in children with congenital absence of the thyroid. These may be skeletal or may affect other organic systems. Those associated with abnormalities of the brain are of practical importance, since they may cause spastic paraplegia, athetosis, ataxia and convulsions. Whether these symptoms are due to the cretinism is a question, but at any rate they do not respond to its specific treatment.

**Differential Diagnosis.** Since the symptoms appear gradually, the early diagnosis of hypothyroidism may be difficult, but one should think of it in any case of retarded growth or mental development. If diagnosis and treatment are delayed, the infant may suffer much harm. In mild cases roentgenographic evidence of retardation of ossification is an important diagnostic aid. Elevation of the cholesterol and carotene levels of the blood and reduction of the serum phosphatase

support the clinical diagnosis. A low protein-bound iodine and a low radio-iodine uptake are diagnostic.

Since *mongolism* is apparent at birth, it can usually be readily differentiated from sporadic cretinism, whose manifestations develop during the first few months of postnatal life (see Table 112, p. 1134).

*Gargoylism* can be mistaken for cretinism, since the stunted growth, the retarded mental development, the thickness of the skin, the shortness of the extremities and the appearance of the hand form a syndrome which resembles cretinism on superficial examination. Roentgenograms of the bones, enlargement of the spleen or liver, cloudiness of the cornea and an adequate PBI level make the diagnosis of gargoylism.

In *chondrodystrophy* there is shortness of the extremities combined with enlargement of the head and flattening of the bridge of the nose as in cretinism, but there is no other resemblance. *Pituitary dwarfs* show retarded growth, and often the closure of the fontanel and ossification are delayed, but other signs of hypothyroidism are absent.

**Prognosis.** Without treatment cretins frequently die of intercurrent infections in childhood. Those who live become mentally deficient dwarfs. Normal physical, sexual and osseous development is attained with thyroid treatment and may proceed satisfactorily even after a delay in starting treatment. The mental development, however, is often not so satisfactory. Although it is generally stated that the results are better the earlier in life treatment is started, the correlation between mental development and adequacy of therapy is not too good. It has been estimated that about half of infants with hypothyroidism who are treated adequately before six months of age will achieve an intelligence quotient of 90 or more. Some infants with mild hypothyroidism will achieve an equal mental status, even if treatment is delayed a year or two. Children who acquire hypothyroidism after two years of age have a good prognosis for mental development, if treatment is adequate. There is suggestive evidence that impairment of cerebral development in the cretin may begin in some instances in utero.

**Treatment.** Desiccated thyroid in tablet form is given orally to cretins and children with hypothyroidism as substitution therapy. It must be given continuously, but the dose may need to be altered; increased doses may be required for the periods of growth, puberty

and reproduction. It requires some time to saturate the tissues of the body with the hormone, which then has a cumulative effect. Thus an immediate effect of therapy cannot be expected, and the dose should not be judged by the results after a few days of administration. The total daily requirement is given as a single dose. As soon as the diagnosis of cretinism is made an initial dose of 0.015 gm. ( $\frac{1}{4}$  grain) of desiccated thyroid (U.S.P.) should be given daily. If this dose is well tolerated, 0.03 gm. per day may be prescribed one week later. Further increases of the drug should be made at intervals of one or two weeks, and the increment should not exceed 0.015 to 0.03 gm. In the first year of life the dose should be 0.045 to 0.090 gm. ( $\frac{3}{4}$  to 1.5 grains) daily, and in older children daily doses of 0.12 to 0.2 gm. (2 to 3 grains) will usually prove satisfactory. The dose must be adjusted to the demands of the individual child. Determination of the protein-bound iodine (or butanol-extractable iodine) level is the best laboratory procedure to evaluate the adequacy of therapy. One should attempt to maintain levels between 6.0 and 8.0 micrograms per 100 ml.

Sodium-l-thyroxine given orally is also effec-

tive, but has no advantages over desiccated thyroid. Each 0.1 mg. is equivalent to approximately 0.09 gm. ( $1\frac{1}{2}$  grains) of U.S.P. thyroid. Triiodothyronine also appears to afford adequate replacement therapy, but seems to have no advantages over U.S.P. thyroid. Protein-bound iodine levels are of no value in determining adequacy of therapy when this compound is used.

### ACQUIRED HYPOTHYROIDISM

Symptoms of hypothyroidism, which can become manifest at any age, may be due to primary disturbances of the thyroid by infections, particularly the contagious ones, by operative removal of a lingual or a normally situated thyroid or by unknown causes. Thyroid deficiency may also be secondary to deficiency of thyrotropin in generalized or selective pituitary disturbances. A congenitally hypoplastic thyroid gland may furnish amounts of hormone sufficient for the early periods of life, but a deficiency may develop when the demands on the gland are increased by changes within the organism such as rapid growth and/or increased size. This congenital form, which becomes manifest in later life,

FIG. 341. Acquired hypothyroidism in a girl 6 years of age. Treated with a wide variety of hematinics for refractory anemia for 3 years. Almost complete cessation of growth, constipation and sluggishness of years' duration. Height age, 3 years; bone age, 4 years; sallow complexion, and immature facies with poorly developed nasal bridge. A, Serum cholesterol 501 mg. per 100 ml., alkaline phosphatase 1.8 Bodansky units, radio-iodine uptake 7 per cent at 24 hours, PBI 2.8 micrograms per 100 ml. B, After therapy for 18 months. Note nasal development, increased luster and decreased pigmentation of hair and maturation of face. Height age,  $5\frac{1}{2}$  years; bone age, 7 years. Marked improvement in general condition.

may be misinterpreted as acquired hypothyroidism.

The symptoms depend upon the age of the child and the severity of the destruction. The later in life hypothyroidism is acquired, the less will be the impairment of growth and development. However, myxedematous changes of the skin, constipation, sleepiness and a mental decline may develop. Cessation or retardation of growth in a child whose growth has previously been normal should always alert one to the possibility of hypothyroidism. Obese children are frequently, but erroneously, considered to have hypothyroidism. Most obese children are taller than average, have warm moist skin, ruddy complexion, and normal thyroid function (see Fig. 341).

Deficiency of pituitary thyrotropic factor may be suspected when there are signs of deficiency of other anterior pituitary hormones, such as gonadotropins and corticotropin. It is possible to differentiate primary and secondary hypothyroidism by studying the response of the thyroid to parenterally administered thyrotropin. After an initial study to determine the radio-iodine uptake, TSH is administered intramuscularly for several days, and the radio-iodine tracer study is repeated and compared with the original one. In primary thyroid failure there is little or no change, whereas in hypothyroidism associated with panhypopituitarism or due to selective deficiency of thyrotropin there is a significant increase in thyroid uptake of radio-iodine. Although the optimal dose of TSH to be used for this diagnostic test has not been definitely determined, it appears that 5 to 15 mg. given intramuscularly twice daily for three days is effective.

*Treatment* consists in administration of desiccated thyroid. The dose must be adjusted to the demands of the individual child (see p. 1167). The prognosis with adequate replacement therapy is good.

## GOITER

A goiter is an enlargement of the thyroid gland. Persons with enlarged thyroids may have normal function of the gland (*euthyroidism*), thyroid deficiency (*hypothyroidism*) or overproduction of the hormone (*hyperthyroidism*). Goiter may be congenital or acquired, endemic or sporadic.

### ENDEMIC GOITER

#### (IODINE-DEFICIENCY GOITER)

It is generally assumed that simple goiter is essentially a manifestation of iodine defi-

ciency, but other "goitrogenic" factors may also play a role in its etiology. As a rule the function of the thyroid is not disturbed. The thyroid hormone circulating in the blood is adequate, and the serum iodine values are within the normal range.

The hormone used in the metabolism of the tissues is decomposed and the liberated iodine returned to the thyroid; only small amounts of iodine are lost in the secretions and excretions of the body. These small amounts (estimated to be 50 micrograms daily) are ordinarily replaced by the iodine contained in food and water. However, water and food are deficient in iodine in certain areas, such as the northwestern states and the states surrounding the Great Lakes in the United States. The dietary iodine deficiency is even greater in certain mountainous districts in Switzerland, Austria and France, in the Carpathian, Himalayan and Andean mountains, and in many other regions. If food and water are derived entirely from an area in which the soil is poor in iodine, as in isolated communities in the mountains, the entire population may be affected by iodine deficiency, and goiter becomes endemic. Seawater is rich in iodine, and the iodine content of fish and shellfish is also high. Endemic goiter is therefore rare in populations living along the sea. Food derived from the sea is now shipped to distant places inland, and the iodine content of the diet in deficient areas may thereby be improved. In persons who have only a mild deficiency of iodine the enlargement of the thyroid does not become noticeable except when there is an increased demand for the hormone. This is true during the periods of growth and adolescence and in pregnancy. In regions of moderate iodine deficiency, goiter may be observed in school children. It may disappear when maturity is reached and reappear in pregnancy and during the period of lactation. In areas of iodine deficiency many more girls have goiters than do boys.

**Pathogenesis.** The thyroid stores and produces the thyroid hormone. If there is a shortage of one of the essential materials (iodine), the demand can be satisfied by increased efficiency in production and prevention of waste. Iodine liberated in the tissues is returned quickly to the gland, which resynthesizes the hormone at a higher rate than normal. This increased activity is achieved by a compensatory hypertrophy and hyperplasia. The cells become enlarged and change from a flat-cuboidal to a columnar shape. As soon as the

hormone is formed it must be transported to the tissues, and storage of colloid does not occur. The radio-iodine uptake is frequently elevated and may be 70 per cent or more of the administered dose. Usually during childhood the thyroid continues to function even when there is a scarcity of iodine; thus the demand of the tissues for thyroid hormone is satisfied. Decompensation and hypothyroidism as a result of iodine deficiency in children are rare in this country.

**Clinical Manifestations.** In simple goiter the thyroid gland becomes palpable and visible; its surface is smooth and its consistency soft. The enlargement is usually moderate, and pressure symptoms are rare. Bruits may often be heard on auscultation of the gland. Signs of endocrine disturbance usually do not develop, and the basal metabolic rate remains within normal limits.

**Differential Diagnosis.** Simple goiter must be distinguished from toxic goiter. In toxic goiter the increased basal metabolic rate and the symptoms of toxicity establish the diagnosis. In endemic cretinism the goitrous person is mentally retarded, and signs of hypothyroidism are present. Carcinoma and chronic lymphocytic thyroiditis must also be considered in the differential diagnosis.

**Prevention.** Simple goiter is prevented by regular ingestion of small amounts of iodine. In regions where a shortage exists the diet should be supplemented. Iodized salt, which in this country contains 0.01 per cent of potassium iodide, provides one of the best forms of prophylaxis.

**Treatment.** Tablets containing 10 mg. of iodine are given once a week until the enlargement of the thyroid disappears.

#### ENDEMIC CRETINISM

**Etiology.** Endemic cretinism is rare or nonexistent in the United States. Wherever endemic goiter occurs in mountainous regions, endemic cretinism is frequently found. Although a definite correlation exists between the iodine deficiency in the soil, food and water of these regions and endemic goiter and cretinism, it does not entirely explain the etiology of cretinism. Iodine deficiency is believed to lead to goiter in the mother and, if the deficiency persists during pregnancy, to cretinism in some of her children. It is possible, however, that in addition to iodine deficiency other unknown factors contribute to the causation of cretinism.

The endemic cretin, in contrast to the athyroid sporadic cretin, is usually born with

an enlarged thyroid gland. Such a congenital goiter is poor in colloid; the cells appear large and crowded, and the blood vessels distended and filled with blood. Compression of the trachea may interfere with respiration in early infancy and be a lethal factor. In those children who survive, degenerative processes in the thyroid result in atrophy of the glandular tissue and in hypothyroidism. At such times goiter may be absent.

**Clinical Manifestations.** The symptoms of endemic cretinism are dwarfism, retarded ossification, epiphysal dysgenesis, myxedema, deafness, dental caries, constipation, delay in sexual maturation and mental deficiency.

**Prevention.** Endemic goiter and congenital goiter, as well as endemic cretinism, are disappearing in goitrous areas where iodized salt is used by most of the population.

**Treatment.** Iodine has no effect, since synthesis of thyroid hormone is not possible in the absence of functioning glandular tissue. Substitution therapy is required, and if desiccated thyroid is administered soon after birth, some symptoms of hypothyroidism can be avoided, but mental retardation cannot be prevented by treatment after birth.

#### SPORADIC GOITER

This type of goiter is seen most frequently in puberal girls. It occurs sporadically in areas where the food and water are not deficient in iodine and where goiters are uncommon. One can rarely elicit a history of reduced iodine intake or of ingestion of excessive amounts of known goitrogenic foods such as turnips, rutabagas or cabbage. The etiology is not understood, but it has been suggested that the goiter may be a manifestation of increased demand for thyroid hormone during adolescence, which the glands overcome by hyperplasia in response to increased secretion of thyrotropin.

Recent studies indicate that some instances of sporadic goiter are the result of an intrinsic biochemical defect in the synthesis of the thyroid hormone. When this derangement is slight, compensatory hypertrophy of the thyroid gland is sufficient to maintain the patient in a euthyroid state. Severe defects of thyroid synthesis result in goitrous cretinism (see p. 1167).

Sporadic goiter may also be iatrogenic. Prolonged administration of para-aminosalicylic acid or cobalt and externally applied resorcinol have been reported to cause goiter. In allergic children treated for a long time with Lugol's solution, potassium iodide or syrup of hydriodic acid goiter has occasion-

ally developed. In such instances hypothyroidism eventually develops if the goitrogen is not discontinued.

The goitrous thyroid is diffusely enlarged and soft. The enlargement is usually slight or moderate, but occasionally is marked. No constitutional symptoms are present, and only rarely are there local pressure symptoms. Many patients show an elevated twenty-four-hour radio-iodine accumulation. Other studies of thyroid function are usually within normal limits.

Small goiters require no treatment; the larger ones are treated primarily for cosmetic reasons. The treatment of choice is desiccated thyroid, 60 to 120 mg. a day, which may be continued for a year or longer as needed.

If remission does not occur within three to six months, it is unlikely that continued treatment will be effective. In most instances a permanent remission is obtained.

#### CONGENITAL GOITER

Sporadic congenital goiter is being reported with increasing frequency; at least half the cases are accounted for by the administration of propylthiouracil and/or iodine during pregnancy for the treatment of thyrotoxicosis. Administration of iodides for asthma during pregnancy has also occasionally resulted in

thyroid enlargement of the newborn infant. Although some congenital goiters appear to be the result of a defect in synthesis of thyroid hormone, no etiologic factor has been established in a number of them.

The enlargement of the thyroid at birth may be sufficient to cause severe respiratory distress and interfere with nursing. The head may be maintained in extreme hypertension. Death has been attributed to respiratory embarrassment. When respiratory obstruction is severe, partial thyroidectomy may be helpful; tracheotomy has not been. Administration of thyroid hormone generally hastens the disappearance of goiter.

#### THYROIDITIS

Thyroiditis in children is rare. Specific etiologic agents such as cat-scratch disease, tuberculosis and mumps virus have been reported to cause thyroiditis. In most instances the etiology is not known.

*Suppurative thyroiditis* is usually preceded by a respiratory tract infection or is secondary to trauma. When suppuration occurs, incision and drainage and administration of antibiotics are indicated.

*Chronic lymphocytic thyroiditis (struma lymphomatosa, Hashimoto's struma)* occurs occasionally in childhood. The onset is usually between the sixth and tenth years of life. It occurs almost exclusively in females, usually being manifest as a painless, slowly growing mass in the neck. Physical examination reveals a firm gland, which is lobular and may give the impression of being nodular.

Most patients are euthyroid, but some show clinical and laboratory signs of hypothyroidism. Pathologically, the outstanding feature is diffuse lymphocytic infiltration throughout the thyroid gland with lymph follicle formation and only a slight increase in fibrous tissue.

Recent studies have shown that this type of goiter is associated with elevation of serum gamma globulins, with positive thymol and zinc sulfate turbidity tests and with colloidal gold flocculation. Auto-antibodies against thyroglobulin have been demonstrated in the serum of such patients, and the serum protein changes are thought to result from the auto-immunization. It has been suggested that destruction of the gland results from progressive interaction of the auto-antibody with thyroglobulin in the gland. These aberrations may be of diagnostic value and obviate the need for surgery. In the absence of these diagnostic aids a biopsy is indicated to elim-

FIG. 342. Congenital goiter in 6-weeks-old infant with increasing respiratory distress and cervical mass since birth. Operation revealed large goiter which almost completely encircled the trachea. Note anterior deviation and posterior compression of the trachea. Partial thyroidectomy completely relieved symptoms. No etiology for goiter found. It is apparent why a tracheotomy is not adequate treatment for these infants.

inate the possibility of a malignant neoplasm.

Replacement therapy with thyroid is indicated.

### EXOPHTHALMIC GOITER; HYPERTHYROIDISM

(THYROTOXICOSIS, TOXIC GOITER,  
GRAVES' DISEASE, BASEDOW'S DISEASE)

**Etiology.** Hyperthyroidism and thyrotoxicosis are terms for an anomaly of the thyroid gland which is characterized by excessive liberation of thyroid hormone. As a rule such patients have a goiter, which is usually diffuse, but may be nodular. Exophthalmos may or may not be present.

The etiology is not known. The uptake of iodide by the hyperactive gland is excessively rapid, as is the production of hormone, which is released rapidly into the blood. The iodine and the thyroxin content of the hyperthyroid gland is low.

Hyperthyroidism is uncommon in children. Approximately one per cent of all cases occur under the age of fifteen years, and, of these, 80 per cent occur between the ages of ten and fifteen years. The disease has been observed, however, in infants as young as one year. The incidence is about seven times higher in girls than in boys. Exophthalmic goiter may be found in several members of a family. Infectious diseases or psychic trauma may precipitate the disease. Hyperthyroidism occurs occasionally with polyostotic fibrous dysplasia and sexual precocity (p. 1246).

**Pathologically,** there is hypertrophy, hyperplasia and striking vascularity. The epithelial cells are high and columnar, and the colloid is reduced. In some instances there are also areas of adenomatous tissue which may contain colloid.

**Clinical Manifestations.** The earliest signs in children may be emotional disturbances accompanied by motor hyperactivity. The children become irritable and excitable and cry easily. Their schoolwork suffers, and their restlessness, which resembles that of chorea, causes conflicts. Tremor of the fingers can be noticed if the upper extremity is extended. There may be a voracious appetite combined with loss or no increase in weight. The thyroid is enlarged, visible and palpable, and bruits are usually audible over it. Exophthalmos is noticeable in the majority of cases. *Graefe's sign* (lagging of the upper eyelid as the eye looks downward), *Moebius' sign* (inability of convergence) and *Stellwag's sign* (retraction of the upper eyelid and infrequent blinking) may be present. The skin is smooth

and flushed, and excessive sweating is noticed. Muscular weakness progresses as the disease continues. Tachycardia, palpitation, dyspnea and cardiac enlargement and insufficiency cause discomfort and may endanger the patient's life. The systolic blood pressure and the pulse pressure are increased. Children with hyperthyroidism are usually tall, their osseous development is advanced for their age, but sexual maturation is delayed.

The basal metabolic rate is increased from +20 to +60 per cent. The glucose tolerance is decreased, and there may be glycosuria. Lymphocytosis is found in the blood. The cholesterol tends to be low. The urinary output of creatine is increased and that of creatinine diminished. The protein-bound iodine in the serum is high, most levels being in the range of 10 to 20 gammas per 100 ml. Uptake of radioactive iodine is rapid, the majority of patients having an uptake of over 40 per cent. Diagnostic doses of radio-iodine should be kept as small as possible.

**Differential Diagnosis.** Simple goiter may be as large as or larger than the goiter of hyperthyroidism, and a bruit may be heard on auscultation of the gland, but the absence of toxic symptoms determines the differentiation. The cardiac symptoms may simulate organic heart disease, but the presence of goiter and exophthalmos favor hyperthyroidism. The restlessness and agitation may suggest chorea. The clinical pattern of pheochromocytoma may resemble that of hyperthyroidism in many respects, but the elevation of blood pressure is greater, may be paroxysmal and responds to adrenolytic drugs.

**Prognosis.** Recovery is often possible with medical treatment. Untreated severe cases may develop psychotic patterns; toxic crises in which vomiting, diarrhea, fever and prostration dominate the clinical picture may terminate in death. When operation is required, preparatory treatment with iodine renders the prognosis favorable in most instances.

**Treatment.** There is general agreement that most children with thyrotoxicosis should be given a trial of medical therapy before surgery is considered. During adolescence in particular an attempt should be made to tide the child over this period of rapid growth with antithyroid drugs in the hope of inducing a permanent remission.

Excitement must be avoided, and an adequate and liberal diet should be prescribed. Supplementary vitamins are indicated, and phenobarbital may be needed until the dis-

ease is under control. A sympathetic understanding by the family of the physical and emotional problems is essential.

Of the antithyroid drugs, propylthiouracil, an effective and relatively safe agent, is the one most widely used. Methimazole (1-methyl-2-mercaptoimidazole) is also effective and approximately twenty times as potent as propylthiouracil. These compounds inhibit incorporation of trapped inorganic iodide into organic compounds and thus produce a progressive lowering of circulating thyroid hormone. Toxic reactions occur with about equal frequency with the two drugs. Because of variations in the responses of different patients, the initial dose of these drugs should be small; for example, 50 mg. of propylthiouracil three times daily. Subsequently the dose is increased as indicated; as much as 500 mg. or more a day may be necessary. Smaller initial doses should be used in early childhood. Because of the rapid excretion of propylthiouracil, an attempt should be made to space doses at intervals of eight hours (e.g., on arising, midafternoon and bedtime). Overdosage can lead to a hypothyroid state and should be avoided. Clinical response becomes apparent in two to three weeks, and adequate control in two to three months.

The thyroid frequently becomes larger after initiation of treatment, but eventually it usually decreases in size. The drug should be continued for at least a year after complete control of the disease has been obtained, and then should be discontinued slowly. Approximately 75 per cent of children will have a permanent remission; if a relapse occurs, it will usually appear within three months and almost always within six months after therapy has been discontinued. Therapy may be resumed in case of a relapse. In puberal children it may be advisable to continue treatment throughout early adolescence.

Less than 2 per cent of patients treated in this manner have minor toxic reactions such as fever, skin rash, nausea, diarrhea, abdominal cramps and headache. More serious reactions such as agranulocytosis are rare.

Operation is indicated when adequate co-operation for medical management is not possible or when medical management has failed. Subtotal thyroidectomy, a rather safe procedure, is performed after the patient has been brought to a euthyroid state. This may be accomplished with propylthiouracil or methimazole over a two- to three-month period. After a euthyroid state has been attained 5 drops of a saturated solution of potassium

iodide per day are given in addition for two weeks prior to operation. The iodide decreases the vascularity of the gland. Complications of surgical treatment include recurrence of thyrotoxicosis, hypothyroidism, hypoparathyroidism and paralysis of the vocal cords.

Radioactive iodine should not be used for treatment in children because, theoretically, permanent harmful irradiation effects might occur either on the thyroid or on other tissues. To date there have been no reports of carcinomas occurring in any thyroid treated with radio-iodine. However, a period of observation of many years will be needed to exclude this possibility. In a patient in whom medical treatment is not feasible and operation is contraindicated or refused, radio-iodine may have to be resorted to. It has been used with success in cases complicated by other disorders such as rheumatic heart disease or when cooperation for long-term medical management was not possible.

### CARCINOMA OF THE THYROID

Carcinoma of the thyroid in children is not rare. Winship has collected 334 cases from published and unpublished sources. The etiology is unknown. Contrary to popular belief, the incidence in goitrous areas is no higher than in nongoitrous areas. It has been suggested that there may be some relation between cancer of the thyroid and irradiation to the neck or thymus. A history of irradiation of the thymus was obtained in approximately 20 per cent of the cases of carcinoma of the thyroid in children in the United States.

Girls are affected more often than boys. Although the onset is usually after the age of nine years, it may be as early as the first year of life. The first evidence is usually a painless nodule in the thyroid. However, metastases in cervical lymph nodes are the initial sign sufficiently often to warrant including cancer of the thyroid in the differential diagnosis of all masses in the neck. The most common site of distant metastases is in the lung, where they may be present without any clinical manifestations. On the roentgenogram the pulmonary lesions appear as diffuse miliary or nodular infiltrations located principally in the basal portions. They may be mistaken for tuberculosis or histoplasmosis. Carcinoma of the thyroid frequently grows slowly and may even remain dormant for years. Small cell carcinomas of the thyroid, however, frequently have a rapidly fatal course.

There is some disagreement about the indications for diagnostic resection of nodules in the thyroid. Some, including the authors, believe that every identified nodule should be removed and examined, since the incidence of carcinoma in nodules of the thyroid in children is estimated to be as high as 70 per cent. However, Astwood suggests treatment with 120 to 250 mg. of thyroid daily on detection of a nodule to determine whether its growth can be suppressed. Only if the thyroid continues to grow during such therapy does he believe that resection is indicated.

The treatment of proved carcinoma of the thyroid is also controversial. One group recommends thyroidectomy (hemithyroidectomy with removal of the isthmus if the disease is unilateral), dissection of enlarged cervical nodes and postoperative roentgen therapy. Another group recommends total thyroidectomy and regional dissection of lymph nodes even though there is no evidence of involvement of them. Even inoperable tumors should be removed as completely as possible together with any existing normal thyroid tissue in preparation for the possible use of radioiodine. Radioiodine should be used only when the lesion cannot be removed surgically and when the cancerous tissue is capable of concentrating cancerocidal doses of the drug. Regression of extensive pulmonary metastases has been observed following the use of radioiodine.

Although it has not been established with certainty that irradiation of the thyroid area (thymus) constitutes the carcinogenic agent, it seems clear that the indiscriminate use of irradiation such as with roentgen rays or radioiodine should be scrupulously avoided.

# DISORDERS OF THE PARATHYROID GLANDS

Disturbances of the parathyroid glands with gross morphologic changes are not frequent in infants and children. In some clinical syndromes the parathyroids are the site of primary disturbance; in others they are only secondarily affected.

Though complete absence of the parathyroid glands has been reported, there may be some doubt of the authenticity of the observations, since the small glands may have been overlooked. Variations in number are not uncommon; more than four glands are frequent, but rarely are there less than four.

**Function.** The parathyroid hormone is an integral factor in the maintenance of calcium and phosphorus balance. This is its principal known function, although indirectly through its effect on calcium metabolism it is a controlling factor in the structure of bone, in the regulation of neuromuscular activity, in the conduction of cardiac impulses, in the coagulation of blood, in the permeability of cellular membranes, and perhaps in the regulation of other functions of the body. There is no known tropic hormone from the anterior pituitary gland which stimulates the parathyroid glands. As far as is known the parathyroid glands respond directly to tissue calcium and phosphorus requirements.

If administration of parathyroid extract is discontinued in a parathyroidectomized person, there is a decrease in the urinary excretion of phosphorus and a rise in serum phosphorus which is quickly followed by a fall in serum calcium and a decrease in urinary excretion of calcium. When parathormone therapy is resumed, these metabolic alterations are reversed. It is generally agreed that a fall below the usual serum calcium level of 10.5 plus or minus 1 mg. per 100 ml. provides the stimulus to the gland to free stored calcium. The calcium in the blood is principally in two forms, calcium ions and calcium proteinate. Since the total serum calcium concentration may be reduced by a decrease in the serum protein level, the ionized or active serum calcium cannot be evaluated adequately without knowledge of the concentration of serum protein (see Nomogram, p. 1407).

It is generally accepted that there are two distinct actions of parathormone. It has a direct action on the renal tubular mechanism, causing a phosphate diuresis by the kidney.

It also causes direct resorption of bone, possibly through direct action on the matrix. Because commercially available parathyroid hormone shows two components on electrophoresis, it has been suggested that there may be two parathyroid hormones.

## HYPOPARATHYROIDISM

Hypofunction of the parathyroid glands is manifest clinically as tetany (p. 1110). It may be primary or secondary. Temporary dysfunction is observed in so-called tetany of the newborn (p. 342). Secondary hypoparathyroidism is observed at times in association with deficiency of vitamin D (p. 378) and with celiac disease (p. 723). Primary and permanent lack of function occurs after surgical removal, traumatic destruction or atrophy of the glands.

**Surgical Tetany.** Removal or damage of the parathyroid glands may occur as a complication of thyroidectomy. This is seen in a small percentage of thyrotoxic patients treated by partial thyroidectomy, and in a much larger percentage of patients with carcinoma of the thyroid subjected to total thyroidectomy. Hypoparathyroidism has developed even in patients in whom the parathyroid glands had been identified and left undisturbed at the time of operation. This, presumably, is the result of interference with the blood supply and/or of postoperative edema and fibrosis. Symptoms of tetany may occur abruptly postoperatively and be permanent or temporary. In some instances symptoms develop insidiously and go undetected until months after thyroidectomy. Occasionally the first evidence of secondary hypoparathyroidism may be the development of cataracts.

All patients subjected to thyroidectomy should be carefully studied to determine the status of parathyroid function. Treatment is the same as that for primary hypoparathyroidism.

**Chronic Idiopathic Hypoparathyroidism.** The etiology of this condition is obscure; it may be related to idiopathic adrenal insufficiency, since the two conditions may occur in the same patient or may alternate in members of the same family. In at least one example of familial hypoparathyroidism and hypoadrenalism the parents were first cousins.

The majority of reported cases began during childhood and remained unrecognized for many years. In at least one instance the onset was in the neonatal period. Early diagnosis and institution of treatment may forestall permanent physical and mental deterioration.

Convulsions usually dominate the clinical picture. A typical convulsion may begin with abdominal pain followed by general tonic rigidity of the body and of the extremities with retraction of the head, and cyanosis. There is loss of consciousness, and the attacks may occur at intervals of weeks or months. Numbness and tingling of the hands and feet may precede the attacks. Carpopedal spasms and other manifest signs of tetany may be absent for many years. These facts explain why this form of hypoparathyroidism is frequently mistaken for epilepsy. The differentiation from a brain tumor may also be difficult, since the intracranial pressure is frequently increased. Headaches, vomiting and papilledema may be found in patients with convulsions. Roentgenograms may reveal calcifications of the brain which are particularly marked in the basal ganglia. Keratoconjunctivitis, lacrimation, photophobia, corneal ulceration and scar formation occur. Cataract may develop. The skin is dry and scaly, the hair thin and patchy, and complete alopecia may develop. The nails of the fingers appear short, thick and overgrown by skin. The teeth erupt late and irregularly. Enamel formation is irregular, and the teeth may be unusually soft. Monilia infection of the fingernails, tongue and angles of the mouth is common. In cases of long standing, mental deterioration occurs.

The serum calcium is low (5 to 7 mg. per 100 ml.) and the phosphorus elevated (7 to 12 mg. per 100 ml.). The serum phosphatase is normal or low. The Sulkowitch test (p. 1221) of the urine is negative for calcium. Even moderate amounts of calcium in the urine are strong evidence against hypocalcemia. Roentgenograms of the bones may reveal a generalized increased density limited to the metaphyses suggestive of heavy metal poisoning, or an increased density of the lamina dura. The electrocardiogram typically shows a prolongation of the Q-T interval, which returns to normal when the hypocalcemia is corrected. Electroencephalographic tracings usually show widespread slow activity; the tracings return to normal after the serum calcium has been within the normal range for a few weeks unless irre-

versible brain damage has occurred or unless the parathyroid insufficiency is associated with epilepsy. At autopsy the parathyroids may be absent or replaced by fatty tissue.

**Treatment.** In case of tetany, emergency treatment consists in intravenous injections of 5 to 10 ml. of a 10 per cent solution of calcium gluconate at the rate of 0.5 to 1 cc. per minute. Initially either vitamin D or dihydrotachysterol (A.T.-10) should also be used. Since A.T.-10 acts more rapidly, it is perhaps preferable in the early stages of treatment. Calcium chloride orally in a dilute solution is also useful because it induces a mild acidosis which in itself tends to combat the tetany. It should not be administered parenterally because it results in thrombosis when given intravenously and in sloughing when given subcutaneously. Foods with a high phosphorus content, such as milk, eggs and cheese, should be eliminated from the diet.

Dihydrotachysterol may be given initially in doses of 1 to 4 cc. daily. Maintenance therapy consists in oral administration of vitamin D in daily doses of 50,000 to 250,000 U.S.P. units. After the initial period of standardization, calcium should be given orally in the form of calcium gluconate or calcium lactate.

Clinical evaluation of the patient and frequent determinations of the serum calcium are indicated in the early stages of treatment in order to determine the dosage requirements of vitamin D and of calcium. Maintenance treatment can be continued for many years, and the patient can estimate the urinary excretion of calcium by the Sulkowitch test (p. 1221). A moderate amount of calcium should be excreted in the urine. Most of the symptoms of hypoparathyroidism disappear under the treatment outlined. If hypercalcemia occurs, vitamin D should be discontinued and resumed at a lower dose when the serum calcium level has returned to normal. In cases of long standing, repair of cerebral or dental changes may be impossible. Development of pigmentation or lowering of the blood pressure indicates beginning adrenal insufficiency and requires specific treatment (p. 1182).

**Pseudohypoparathyroidism.** This syndrome, first described by Albright in 1942, is a familial disorder of unknown etiology. To date over forty cases have been reported. In contrast to the situation in idiopathic hypoparathyroidism, there is an adequate production of parathyroid hormone, and histo-

logically the parathyroid glands are normal or hyperplastic. It is believed that the chemical disturbance is due to a failure of the end organs, particularly of the kidney, to respond to parathyroid hormone (phosphate diuresis does not occur after its administration, as is normally the case [Ellsworth-Howard test]). Albright has termed this type of end organ resistance "Seabright-bantam syndrome" because in this breed of fowl the rooster fails to develop male characteristics, owing to failure of the end organs to respond to male sex hormones.

In addition to clinical and chemical findings similar to those of idiopathic hypoparathyroidism, these patients are characterized by a short, stocky build and a round face. Growth failure may be striking, and there is a tendency to brachydactylia. The metacarpals are more often involved than the metatarsals but the second metacarpal is often not affected, and, as a result, the index finger may be longer than the middle finger. There may be other skeletal abnormalities, such as short and wide phalanges, bowing and gnarling of the radius and ulna, and general demineralization of the bones. In addition to calcifications in the basal ganglia, these patients almost characteristically have calcium deposits and metaplastic bone formation subcutaneously. Mental retardation is common and may be due to brain damage resulting from repeated seizures.

The chemical disturbance characteristically does not respond to parathyroid extract, but does to vitamin D. Therefore *treatment* is the same as described for idiopathic hypoparathyroidism.

"Pseudo-pseudohypoparathyroidism." In this disorder the usual anatomic stigmata seen in pseudohypoparathyroidism occur, but the serum calcium and phosphorus levels are normal. The diagnosis is established by roentgenographic demonstration of typical ossification and by demonstration of a phosphate diuresis following administration of parathyroid hormone (Ellsworth-Howard test).

## HYPERPARATHYROIDISM

Adenomas, hypertrophy or hyperplasia of the parathyroids may produce increased amounts of parathormone, which result in a tendency to raise the serum calcium level and to lower the serum phosphorus. If such overproduction of parathormone occurs in a basically normal organism, then more hormone is re-

leased than is needed and a state of "primary hyperparathyroidism" results. If, however, more hormone is released into an organism which is metabolically disturbed and requires more hormone for compensatory purposes, then one speaks of a state of "secondary hyperparathyroidism." In primary hyperparathyroidism the surplus of hormone is harmful, and treatment is aimed at reduction of the hormone to normal levels. In secondary hyperparathyroidism the surplus of hormone is beneficial or at least necessary, and reduction would be harmful. Treatment of secondary hyperparathyroidism must aim at removal of the basic disturbance. Chronic renal disease, rickets and celiac disease are disorders which require compensatory secondary hyperparathyroidism.

### PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is rare in children. In older children the manifestations resemble more or less those in adults, but the symptoms in infants may differ greatly.

Hyperparathyroidism may be due to a single or to multiple adenomas or to idiopathic hypertrophy and hyperplasia of all four parathyroid glands. Hyperplastic glands may be enlarged to about 100 times the normal, and the cells may also be enlarged in volume.

In hyperparathyroidism the serum calcium is elevated, at times to 16 to 20 mg. per 100 ml. The serum phosphorus is reduced to 3 mg. per 100 ml. or below; in cases with skeletal involvement the serum phosphatase is increased. A normal total serum calcium value does not exclude primary hyperparathyroidism, since an increase of the ionized calcium fraction may be masked when the serum protein and the calcium proteinate are reduced. The urinary excretion of both calcium and phosphorus may be increased. Low levels of serum magnesium have been reported in association with primary hyperparathyroidism.

The osseous changes are characterized by increased absorption or osteoclastic activity. There are also signs of repair or osteoblastic activity, but the former process predominates. Tumors consisting of osteoclasts and osteoblasts are termed benign giant cell tumors or osteoclastomas. Secondary changes may lead to degeneration and softening of abnormal bone tissue, and cysts of various sizes may be formed. Fractures may occur in areas of abnormal bone structure. The cellular bone marrow is replaced by fibrous tissue, a change

once considered characteristic of generalized osteitis fibrosa cystica. It is now interpreted as a nonspecific reaction to rapid absorption of the osseous structure, which is also found in polyostotic fibrous dysplasia, Paget's disease and other osseous disorders.

The renal changes are due to the increased demand for excretion of calcium and phosphorus. Renal stones are frequently formed, and calcium deposits in the pyramids may interfere with renal function. Anuria and renal insufficiency may result from the nephrolithiasis and nephrocalcinosis.

**Clinical Manifestations.** Generalized osteitis fibrosa cystica was the first recognized manifestation of primary hyperparathyroidism. Later it was recognized that renal changes may occur with or without skeletal involvement. Gastrointestinal symptoms may also be the only expression of hyperparathyroidism.

Osseous changes may be responsible for pain in the back or extremities, disturbance of gait, deformities, fractures and tumors. There may be decrease in height resulting from compression of vertebrae, and the patient may be bedridden. In infants enlargement and tenderness of the epiphysal regions have been observed; the anterior fontanel may be large and bulging. These clinical findings suggest rickets. Muscular weakness, anorexia, nausea, vomiting, loss of weight, emaciation and fever are general symptoms. Mental retardation or deterioration, generalized seizures, headache and blindness may also occur. Renal, ureteral or vesical calculi develop and are responsible for renal colic and hematuria. Calcium may also be deposited in the renal parenchyma, resulting in so-called nephrocalcinosis, which can be recognized on the roentgenogram. The clinical manifestations are those of the nephrosclerotic type of renal disease and consist in polyuria, polydipsia, and a urine with a low fixed specific gravity. These symptoms may be present before renal calcification is radiologically demonstrable. Renal function is progressively diminished. A high incidence of duodenal ulcers in adults with primary hyperparathyroidism and at least one case in a child have been reported.

Roentgenograms reveal generalized rarefaction of the bones, thinning and scalloping of the cortex, cysts, tumors, fractures and deformities. Calcification of soft tissues has been observed. In infants cupping and fraying are seen at the ends of the shafts, and the

distance between the calcified diaphysis and the epiphysis is increased. These findings, as well as flaring of the ends of the ribs, and scoliosis are suggestive of rickets. In the adult type the skull may show gross trabeculation or a granular appearance resulting from focal rarefaction. In infants there may be increased digitations, and vascular and intracranial calcifications have been observed. Subperiosteal resorption of bone is a common finding and is seen most frequently along the margins of the phalanges of the hands. Disappearance of the lamina dura is another common finding.

**Diagnosis.** Idiopathic hypercalcemia of infancy may be easily confused with hyperparathyroidism. The signs and symptoms are the same in both disorders, and both are characterized by hypercalcemia. The serum phosphorus level is normal or slightly elevated in *idiopathic hypercalcemia* and depressed in ordinary hyperparathyroidism. Roentgenographically, the increased bone density of idiopathic hypercalcemia contrasts strikingly with the rarefaction of primary hyperparathyroidism.

*Hypercalcemia*, of any etiology, results in a similar clinical pattern. In most of these disorders, as in vitamin D intoxication, the roentgenograms show increased density of bone.

*Hypophosphatasia*, especially when severe, is frequently associated with mild to moderate hypercalcemia. The serum phosphorus is normal, and the serum alkaline phosphatase activity is depressed. Roentgenograms of the bones may show complete disappearance of the zone of provisional calcification and lack of calcification of the metaphysal bone. In *rickets* the serum calcium is normal or low, which helps in differentiating it from primary hyperparathyroidism of infants.

Polyostotic fibrous dysplasia, osteogenesis imperfecta, xanthomatosis, Gaucher's disease and metastases of malignant neoplasms have normal calcium and phosphorus levels of the serum and sufficiently characteristic roentgenographic findings to cause little difficulty in diagnosis. The differentiation from secondary hyperparathyroidism is discussed below.

**Prognosis.** The prognosis is good if the disease is recognized early, and a parathyroid adenoma or adenomas can be demonstrated and removed. When extensive osseous lesions are present, permanent deformities may persist; when renal damage has occurred, the prognosis is less hopeful.

**Treatment.** Surgical exploration is indicated in all but completely hopeless cases. All glands should be carefully inspected, and any existing adenoma should be removed or, if there is only generalized hyperplasia, a subtotal parathyroidectomy should be performed. If the serum calcium level is exceedingly high, calcium should not be injected postoperatively until the concentration is lowered, or fatal poisoning may result. In the presence of extensive osseous disease and a high serum phosphatase, removal of the entire tumor may result in hypocalcemia and tetany, due to cessation of bone destruction and continuation of bone formation at excessive rates. Owing to this danger, Albright recommends partial removal of the tumor when bone involvement is marked. If, however, the entire tumor should be removed, continuous intravenous administration of calcium gluconate may be required immediately after the operation (see above). Likewise, when there is extensive renal damage, only partial removal of the tumor is recommended. It is thought that a certain amount of hyperparathyroid activity is required in such instances to maintain a normal calcium level.

Under ordinary circumstances average amounts of vitamin D and diets high in calcium and phosphorus should be maintained for several months after the operation.

#### SECONDARY HYPERPARATHYROIDISM

Secondary hyperactivity of the parathyroid glands is commonly observed in chronic renal insufficiency, in vitamin D-deficient rickets and in celiac disease with or without rickets. In each of the latter two intestinal absorption of calcium and phosphorus is deficient, and hypocalcemia and tetany are averted by the increased activity of the parathyroid glands. When the parathyroids fail to respond to the stimulus of the low serum calcium and do not increase their activity to a sufficient extent to maintain a normocalcemia or when they "play out," hypocalcemic tetany results (p. 1110).

#### RENAL DISEASE WITH HYPERPARATHYROIDISM

In many instances of experimental and clinical chronic renal disease an associated hyperparathyroidism has been observed. In renal insufficiency there is usually retention of serum phosphate, and Albright postulates that the hypocalcemia which is secondary to the hyperphosphatemia is the stimulus to increased parathyroid activity. In many, but not in all,

instances there is an associated involvement of the osseous structures.

#### RENAL HYPERPARATHYROIDISM AND BONE DISEASE

(RENAL HYPERPARATHYROIDISM WITH OSTEOPOROSIS [OSTEITIS] FIBROSA CYSTICA [Park and Eliot], RENAL OSTEITIS FIBROSA CYSTICA [Albright], RENAL RICKETS, RENAL DWARFISM, RENAL INFANTILISM)

The multiplicity of terms used for this syndrome is indicative of the lack of complete understanding of its pathogenesis. It is generally agreed that the primary lesion is a renal one. This is in contrast to the renal lesion of nephrocalcinosis which may result from primary hyperparathyroidism.

**Etiology.** Though the renal insufficiency may result from a variety of factors, in children most cases appear to be caused by congenital obstructive lesions of the lower urinary tract. Such lesions include urethrovesical and ureterovesical obstructions and bilateral anomalies of the ureters. In sequence there is dilatation of the structures above the obstruction, hydronephrosis, and finally pressure atrophy of the renal parenchyma. Chronic glomerulonephritis and chronic pyelonephritis are other causes of renal insufficiency leading to secondary hyperparathyroidism.

**Pathology.** It is assumed that hyperphosphatemia is the primary stimulus to increased activity of the parathyroid glands. Whether the increased amount of circulating parathyroid hormone acts directly or indirectly on bone is a moot point. Whatever the mechanism of action, the resulting osseous lesions are histologically similar to those occurring in primary hyperparathyroidism. There is an increased number of osteoclasts, resorption of bone, cystlike spaces and a widespread distribution of fibrous connective tissue in place of marrow. If the onset occurs after endochondral growth is complete or essentially so, the changes are limited chiefly to the shaft. Prior to this time, the younger the child the greater the changes in the epiphyseal areas. In the very young, and especially when the process is rapid, there is an accumulation of proliferative cartilage which is due, not to overproduction, but to continued endochondral growth without conversion of the cartilaginous matrix into bone. The result is a soft epiphyseal plate which is easily distorted, resulting in a rachitic-like appearance. These osseous changes are responsible for the deformities and partly for dwarfing.

**Clinical Manifestations.** The younger the child at the time of development of the osseous lesions, the greater the degree of dwarfing; and the longer the process continues, the greater are the deformities. The clinical and roentgenographic skeletal manifestations are similar to those observed in untreated severe infantile rickets or in vitamin D-refractory rickets. Either the skeletal deformities or the renal symptoms may be the manifestations first observed.

The clinical manifestations of the renal disturbance are essentially those of the nephrosclerotic kidney with progressive loss of ability to concentrate urine, retention of nitrogen and hypertension. In some instances the latter two seem to be less marked than in other comparable chronic disturbances of the kidney.

The results of laboratory examinations vary, but in general there is some degree of nitrogen as well as phosphorus retention. Serum calcium is usually normal or below normal in spite of the increased activity of the parathyroid glands. Renal function tests reveal progressive loss of excretory capacity, and though the blood pressure may not be so high as in other types of chronic renal involvement, there is, as a rule, progressive hypertension. Roentgenograms of the skeleton reveal increased radiolucency of the shaft and rachitic-like deformities at the ends of the long bones. Urographic studies are indicated in all instances.

**Prognosis.** The prognosis is unfavorable, since extensive renal lesions are usually present by the time the diagnosis is suspected. The only hope lies in removal of a urinary

tract obstruction before irreversible renal damage has occurred.

**Treatment.** Obstructive lesions of the urinary tract should be removed as early as possible. A diet high in calcium and low in phosphorus has been recommended. There is apparently no benefit in excessively high doses of vitamin D, and there is danger of overdosage.

## DISORDERS OF THE ADRENAL GLANDS

### GENERAL CONSIDERATIONS

The adrenal gland is composed of two endocrine systems, the chromaffin system contained in the medulla, and the interrenal system of the cortex.

The medulla is of ectodermal origin, and its cells are derived from sympathetic ganglia. The cortex is formed in the embryo by about six weeks' gestation from peritoneal mesothelium and is, therefore, of mesodermal origin.

In a fetus of two months the adrenals are much larger than the kidneys; but from the fourth month the kidneys grow rapidly, and

become about twice as large as the adrenals by the end of the sixth month. At birth the adrenal gland is one third the size of the kidney, and the average combined weight of both glands is 7 to 9 gm. in the full term infant.

The adrenal cortex in the fetus and newborn infant is composed of two histologically distinct components. The outer portion of the gland consists of the true cortex, and the more central portion is known as the "fetal adrenal cortex." At birth the fetal cortex makes up about 80 per cent of the gland. Within a few days after birth it undergoes extensive degeneration which results in a 50

per cent reduction in the total mass by two weeks of age. This fetal cortex completely disappears by one year of age; its physiology is unknown, and its involution is not associated with any recognized deficiency or change in function of the newborn infant.

The true cortex consists of three zones. In the zona glomerulosa, which is situated beneath the capsule, there is an alveolar arrangement of the cells; in the broader zona fasciculata the columns of cells are radially arranged; in the zona reticularis the cells form a network next to the medulla.

**Function.** Removal of both adrenal glands results in death. Vomiting, loss of appetite, thirst, anuria, muscular weakness, tachycardia and fall in blood pressure are followed by coma and death.

The *adrenal cortex* secretes various steroid compounds into the blood stream which are responsible for functions essential to life. The known compounds show different activities when tested in biologic assays. They can be divided into several general groups:

1. *Glucocorticoids.* These steroids have a 21-carbon structure and are also referred to as 17-hydroxycorticoids or 17-hydroxycorticosteroids or simply as corticosteroids. The principal hormone of this group is hydrocortisone, which is also known as cortisol or compound F. Cortisone (compound E) is another steroid in this group.

These substances have carbohydrate-regulating and antiphlogistic properties. The fall of the blood sugar in fasting, adrenalectomized animals is attributed to a lack of these hormones; in their absence, formation of new sugar, gluconeogenesis, from endogenous protein is impaired. The influence of these adrenocortical hormones on fat metabolism is manifest by obesity in children with Cushing's syndrome. There is also experimental evidence indicating that corticosteroids play a role in fat metabolism. Excessive amounts of these substances lead to protein catabolism, osteoporosis and growth failure. They also result in sodium and water retention and loss of potassium.

The corticosteroids and their metabolites are excreted in urine. They can be measured chemically and are interpreted as an index of the production of carbohydrate-regulating hormones by the adrenal gland. Methods are also available for measurement of their blood levels; "normal values" differ somewhat according to the method used. In patients with Addison's disease or pituitary insufficiency the levels of corticosteroids are reduced, and in

those with Cushing's disease they are increased.

The rate of corticosteroid production is under pituitary adrenocorticotropin control. One of the most frequently used tests to assess adrenocortical reserve is the measurement of blood or urinary levels of the corticosteroids before and after the administration of corticotropin.

Many synthetic analogues of cortisone and hydrocortisone are available. Derivatives with an additional double bond in ring A are known as prednisone and prednisolone. They are three to four times as potent in anti-inflammatory and carbohydrate activity as the parent steroids, but have less effect on salt and water retention. Halogenated derivatives are also available. Thus 9- $\alpha$ -fluoro-hydrocortisone is approximately twenty times as active as hydrocortisone in carbohydrate activity, but is more than twenty times as active in salt and water retention. Triamcinolone ( $\Delta$ -1, 9- $\alpha$  fluoro, 16  $\alpha$ -hydroxy-hydrocortisone) is approximately seven times as potent as hydrocortisone and is said to have no effect on retention of water and electrolytes. These analogues are usually used in pharmacologic doses for their antiphlogistic properties.

2. *Mineralo-corticoids.* It has been known for years that the adrenal cortex elaborates a specific hormone capable of prolonging the life of adrenalectomized animals by regulating electrolyte and water metabolism. It was termed the "sodium-retaining" hormone by Albright and "mineralo-corticoid" by Selye. This substance was finally isolated and crystallized in 1953. The following year its chemical structure was found to be the 18-aldehyde of corticosterone, and it was named aldosterone. This substance is now known to be the principal naturally occurring mineralo-corticoid in man.

Since only small amounts of aldosterone occur in natural form and since its large-scale chemical synthesis is not yet economic, the substance is not commercially available. Desoxycorticosterone, however, can be synthesized; it is effective in restoring electrolyte metabolism in adrenal insufficiency, and is used therapeutically for this purpose. Aldosterone is approximately thirty times as active as desoxycorticosterone in its mineralo-corticoid effects. Large amounts of cortisone and hydrocortisone also cause retention of sodium and chloride, but are less than one twentieth as active as desoxycorticosterone.

Aldosterone, unlike the glucocorticoids, is

not under control of corticotropin. Restriction of sodium intake results in increased secretion of aldosterone. There is evidence that secretion of aldosterone is effected mainly by changes in body fluid volume.

3. *Androgens.* Dehydroepiandrosterone is representative of this group. These hormones are capable of increasing retention of nitrogen, potassium, phosphorus and sulfate. They promote growth and have an androgenic effect, properties which are most conspicuous under pathologic conditions when adrenal hyperplasia or adrenal tumors induce precocious growth and development of secondary male sex characteristics. There is evidence that the adrenal androgens are partly responsible for the development of axillary and pubic hair in the female.

Metabolized adrenal androgens are excreted in the urine as 17-ketosteroids. They can be measured and accepted as an index of the production of adrenal androgens in the female. In the male approximately one third of the urinary 17-ketosteroids can be attributed to testicular and two thirds to adrenal androgens. In children under nine years of age the urinary excretion of these substances is small (p. 1195), but there is a constant increase throughout adolescence until adult levels are reached. Under pathologic conditions increased production of adrenal androgens is reflected in increased secretion of urinary 17-ketosteroids.

4. *Estrogens.* Adrenal cortical production of estrogens is most strikingly illustrated in patients with feminizing adrenal cortical tumors (p. 1191).

The *adrenal medulla* consists of irregularly shaped cells and of blood sinuses located between the strands of cells. The secretion of the hormone of the medulla is regulated by the splanchnic nerves. Two hormones are elaborated by the adrenal medulla; epinephrine (Adrenalin) and norepinephrine (noradrenalin; arterenol). Norepinephrine is a primary amine differing from epinephrine only by the absence of an N-methyl group. The proportions of epinephrine and norepinephrine in the adrenal vary at different ages. In early fetal stages there is practically no epinephrine, and even at birth norepinephrine is predominant. In adults norepinephrine makes up only 10 to 30 per cent of the total pressor amines in the medulla. Both epinephrine and norepinephrine increase the mean arterial blood pressure. Norepinephrine accomplishes this without changing the cardiac output. By increasing peripheral vascular

resistance, it increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate and, by decreasing the peripheral vascular resistance, decreases the diastolic pressure. The hyperglycemic and calorogenic effects of norepinephrine are much less pronounced than those of epinephrine. Both hormones are believed to be secreted into the blood stream in approximately the same proportion as elaborated in the adrenal. The variations of the clinical pattern of patients with pheochromocytomas may be explained by the different proportions of the two hormones elaborated. In the majority of these tumors 50 to 90 per cent of the hormonal material recovered is norepinephrine.

### HYPOADRENOCORTICISM

Adrenal insufficiency may result from a wide variety of pathologic lesions of the adrenal glands and is not a rare disorder. The symptoms may be severe or mild, and the deficiency may be temporary or permanent.

**Etiology.** *Adrenal insufficiency associated with congenital adrenal hyperplasia* and characterized by an inability to regulate electrolyte metabolism is probably the most common form. The mechanism for this aberration is still unknown (p. 1188).

*Congenital adrenal hypoplasia* is a much less frequent cause of adrenal insufficiency. Anencephalic monsters consistently have adrenal hypoplasia; it is a rare occurrence in infants with an intact cranium who have pituitary hypoplasia and insufficient secretion of corticotropin. Occasionally it occurs as an isolated congenital anomaly.

*Adrenal hemorrhage* may occur in the neonatal period as a consequence of difficult labor or of asphyxia and occasionally may be sufficiently extensive to result in acute adrenal insufficiency. In some instances the hemorrhage is asymptomatic initially, but progressive fibrosis, calcification or cystic changes may develop. Gradual impairment of function may then culminate in adrenocortical insufficiency in infancy or childhood.

*Bilateral adrenalectomy* or the removal of an adrenal in the absence of the contralateral adrenal will result in adrenal insufficiency. Such a situation may arise after removal of a functioning adrenal tumor, especially one resulting in Cushing's syndrome, when the contralateral adrenal is atrophied (p. 1189).

A recent cause of adrenal insufficiency which may increase in frequency is the *abrupt*

cessation of administration of corticotropin or a corticosteroid. Symptoms are most likely to occur when these substances have been given in large doses for a long time to patients subjected to stressful situations such as severe infections or surgical procedures. Administration of these substances results in impaired pituitary or adrenal cortical function, and their effects may sometimes outlast treatment for a long time.

The term *Waterhouse-Friderichsen syndrome* has been applied to the characteristic state of shock accompanying hemorrhage into the adrenal glands during the course of meningococcemia. Since a similar clinical picture may accompany hemorrhage or necrosis of the adrenals as a result of trauma or fulminating septicemia caused by other organisms, it would appear preferable to include all these conditions under the term *acute adrenal insufficiency*. Occasionally in the course of an acute infection a patient may have all the signs and symptoms of the Waterhouse-Friderichsen syndrome, and yet at autopsy no adrenal hemorrhage is found. A number of investigators have reported cases which at autopsy showed extensive necrosis of the adrenal cortical cells. Measurements of blood corticosteroids in patients with typical symptoms of the Waterhouse-Friderichsen syndrome have usually demonstrated elevated levels indicating normal adrenal function. The circulatory collapse in such instances is probably the result of the severe toxemia and not of impaired adrenal function.

*Chronic adrenal insufficiency*, which develops in infants or children with previously normal adrenal function, is referred to as *Addison's disease*. Tuberculosis, once the most frequent cause of Addison's disease, is no longer a major etiologic factor. At present a "cytotoxic" degeneration or idiopathic atrophy, the cause of which is not known, is noted in most cases. In these cases the glands may be so small that they are not visible at autopsy, and only a few remnants of tissue are found in microscopic sections. The medulla, however, is usually not destroyed, and there is lymphocytic infiltration in the area of the former cortex and in the medulla. Histoplasmosis, coccidioidomycosis, torulosis, amyloidosis, metastatic malignancies and mycosis fungoides have been identified as etiologic agents in adults, but not in children.

Addison's disease resulting from "cytotoxic" degeneration of the adrenal gland has been reported in siblings. In such instances it is not uncommon to find an associated

atrophy of the parathyroid glands. Addison's disease may develop in patients with hypoparathyroidism, and, conversely, hypoparathyroidism in patients with Addison's disease. Siblings are known in which one member had adrenal insufficiency and another hypoparathyroidism. This association of Addison's disease and hypoparathyroidism, and at times of moniliasis, represents a definite genetically determined disorder of variable expressivity.

**Clinical Manifestations.** In older children the onset in the chronic form is gradual with weakness, lassitude, anorexia, loss of weight, vomiting and diarrhea. There may be an intensive craving for salt. Abdominal pain may simulate an acute abdominal process. If water and salt are withheld, dehydration rapidly ensues and circulatory collapse develops, soon to be followed by death. Convulsions, which occur occasionally, have been attributed to hypoglycemia. The pigmentation seen in adults with Addison's disease and consisting of brownish discoloration about the genitals, umbilicus, axillas, nipples and joints may be less striking in children. It may be first apparent on the face and hands or, rarely, be generalized rather than confined to the areas mentioned above. At times vitiligo-like pale spots may be interspersed with the dark areas. In the buccal mucosa the pigmentation is usually bluish-brown. Other physical findings are muscular weakness, general wasting, low blood pressure and microcardia (Fig. 343). In adolescent girls breast development and menstruation begin normally, but axillary and pubic hair are characteristically absent.

Acute adrenal insufficiency, which may be due to adrenal hemorrhage or fulminating infections, may also occur in patients with chronic adrenal insufficiency, when it is known as an *adrenal crisis*. The patient suddenly becomes cyanotic, his skin is cold and clammy and his pulse rapid and thready. The blood pressure falls, respirations are rapid and labored, and the patient sinks into a deep coma. In patients with infections such as meningococcemia, petechial and purpuric rashes appear suddenly over the body, often coalescing into large ecchymotic areas (see Fig. 118, p. 427). In instances of massive hemorrhage the adrenal glands may become palpable. The course of an adrenal crisis is rapid and, if untreated, fatal. In patients with Addison's disease a crisis can be precipitated by infection, trauma, excessive fatigue or drugs such as morphine, barbiturates, laxatives, thyroid hormone or insulin.

FIG. 343. Addison's disease in a 10-year-old boy. On admission he was dehydrated; there was bronzing of the skin and hypotension. Note the deeply pigmented freckles (black freckles) in A, and the microcardia in B; both are characteristic of untreated Addison's disease. Serial measurements of cardiac size are an excellent criterion of adequacy of treatment.

**Laboratory Data.** In Addison's disease the sodium and chloride concentrations in the serum are low and that of potassium is elevated, and there is hypoglycemia. The non-protein nitrogen is usually within the normal range unless the patient is dehydrated. There is an increase in the urinary excretion of sodium and chloride and a decrease of that of potassium. The protein concentration of the plasma is increased. These changes are accentuated during acute crises. Oral administration of glucose may paradoxically result in a fall rather than a rise of the blood sugar level, which may be prolonged and lead to manifestations of hypoglycemia. The urine may contain small amounts of albumin and a few casts; the specific gravity tends to be low.

Roentgenograms of the abdomen occasionally reveal calcified areas in the region of the adrenals, especially when tuberculosis or hemorrhage has been the etiologic factor. A small and narrow shadow of the heart is characteristic of Addison's disease. Abnormalities in the electroencephalogram include absence or a greatly decreased number of low voltage, fast frequency waves. Hypoglycemia may be found after a twenty-four-hour fast. The circulating eosinophils are usually increased in number, but may be normal and even absent during crises. Since pronounced eosinopenia is usually present during acute infections when the function of the adrenal glands is adequate, a normal eosinophil count in the presence of severe infection is suggestive of impaired adrenal function.

Tests of adrenal function have been devised which permit confirmation of the diagnosis. The four-hour corticotropin test is a

useful screening procedure; the number of eosinophils in the blood is counted immediately before and four hours after the intramuscular administration of 25 units of corticotropin. A decrease of less than 50 per cent in the number of eosinophils is suggestive of adrenal insufficiency. One of the most definitive tests of adrenal function is the measurement of urinary and/or plasma levels of corticosteroids before and after the administration of corticotropin in patients with primary adrenal insufficiency. Resting levels of corticosteroids are low in the urine and plasma, and there is no increase after administration of corticotropin. In occasional instances the resting levels of corticosteroids are normal, but there is no increase following administration of corticotropin, indicating the absence of any adrenocortical reserve. A low initial level followed by a significant increase in urinary or blood levels of corticosteroids indicates adrenal insufficiency secondary to pituitary corticotropin insufficiency. The urinary 17-ketosteroids are decreased in men and absent in women, but in children, who normally do not excrete these substances before the age of nine years, no characteristic changes can be expected in Addison's disease.

**Prognosis.** The prognosis in Addison's disease must be guarded despite great advances in therapy. Patients with this disease are similar to those with diabetes in their need for constant supervision; acute crises may develop suddenly and on slight provocation. The patient may become dehydrated quickly during minor infections or during periods of salt restriction, and death may ensue if therapy is not prompt or adequate. The mortality

rate is high in infants and children with acute adrenal insufficiency due to adrenal hemorrhage or infection, but they have an excellent prognosis if they survive the acute episode.

**Treatment.** *Patients with Addison's disease* require replacement therapy for their deficiency of electrolyte-controlling hormones; desoxycorticosterone acetate (DOCA) in sesame oil is administered intramuscularly in single daily injections; maintenance doses usually range from 0.5 to 3 mg. The dose depends upon the intake of sodium chloride, which must be kept constant while the maintenance dose is determined. The daily requirements of sodium chloride are usually 3 to 6 gm. in addition to that contained in the food; sodium chloride can be administered in 1-gm. enteric-coated tablets. During the first few months of treatment there is a gradual decrease in requirements for DOCA. After the maintenance dose has been determined and continued for several months, daily intramuscular administration can be replaced by use of the long-acting preparation, desoxycorticosterone trimethylacetate, a single intramuscular injection of which can provide a constant supply of the hormone for about a month. In lieu of the intramuscular administration, subcutaneous implantation of pellets may be used. A pellet containing 125 mg. of DOCA is equivalent to daily injections of about 0.5 mg. of this drug for about twelve months.

Overdosage with DOCA or salt results in retention of sodium chloride and water and in excretion of excessive amounts of potassium; edema, hypertension, cardiac enlargement and muscular weakness or paralysis are clinical manifestations.

Hydrocortisone should also be administered to all patients with adrenocortical insufficiency in order to maintain normal carbohydrate metabolism and normal vigor. It may be given orally in doses of 5 to 10 mg. twice daily. During situations of stress, such as periods of infection or operative procedures, the dose of hydrocortisone should be increased. Antibiotic therapy is indicated for all infections, even minor ones, since they are poorly tolerated.

*Treatment for acute adrenal insufficiency* or for crises must be instituted immediately and must be vigorous. Five per cent glucose in saline solution is given intravenously at a rate permitting the administration of about 75 ml. per kilogram of body weight per day.

This may be modified, depending on the deficits of the individual. Administration of plasma or, in case of a low hemoglobin level or of adrenal hemorrhage, of whole blood is indicated. Concomitantly a water-soluble form of hydrocortisone, such as the sodium salt of the hemisuccinate, should be given intravenously. High levels may be achieved instantaneously in this manner. No definite dosage schedule has evolved, but large doses can be used safely. As much as 25 mg. for infants and 50 mg. for young children may be given immediately and then continued by intravenous drip on the basis of the foregoing doses for each six-hour period. Intramuscular administration of the steroid should be instituted when intravenous therapy is discontinued. Desoxycorticosterone in oil may be added in doses of 1 to 5 mg., if necessary, to maintain electrolyte balance.

Norepinephrine can be given intravenously in instances of shock and circulatory collapse. Four milligrams per liter may be added to the intravenous solution; the blood pressure should be measured at frequent intervals. Oxygen administration is indicated. In newborn infants with adrenal hemorrhage, vitamins K and C should also be given. In acute adrenal insufficiency associated with infection appropriate antibiotic therapy is essential.

## HYPERADRENOCORTICISM

Three distinct syndromes are attributable to hyperadrenocorticism: the *adrenogenital syndrome*, *Cushing's syndrome* and *primary aldosteronism*. The adrenogenital syndrome is caused primarily by hypersecretion of androgenic hormones and may be congenital or acquired. It may be caused by a defect of steroidogenesis, in which case there is bilateral cortical hyperplasia, or it may be caused by a tumor of the adrenal cortex. Congenital adrenal hyperplasia results in pseudohermaphroditism in the female and in macrogenitosomia praecox in the male. When the disorder develops postnatally, as the result of a tumor or hyperplasia, virilization develops in the female and macrogenitosomia in the male. Cushing's syndrome is the result of hypersecretion of hydrocortisone, which may also be caused by adrenal hyperplasia or a tumor of the adrenal cortex. Primary aldosteronism is caused by excessive secretion of aldosterone, which too may be due to adrenal hyperplasia or a tumor.

FIG. 344. External genitals of a 6-year-old boy with congenital adrenal hyperplasia whose height and weight were those of an average  $8\frac{1}{2}$ -year-old boy. Skeletal maturation was at a level of  $10\frac{1}{2}$  years. The appearance of a few pubic hairs was the reason for seeking medical advice. The testes were relatively small for the size of the penis. Prompt suppression of the elevated urinary levels of 17-ketosteroids and pregnanetriol with cortisone established the diagnosis.

### CONGENITAL ADRENAL HYPERPLASIA

#### (VIRILIZING ADRENAL HYPERPLASIA)

**Pathogenesis.** This disorder is caused by an inborn defect of biosynthesis of certain steroids of the adrenal cortex; the primary disturbance is an inability to synthesize hydrocortisone from its precursor, 17-hydroxyprogesterone, owing to a deficiency of the enzyme "21-hydroxylase." This substance accumulates, is metabolized and excreted in the urine as pregnanetriol. The deficiency of hydrocortisone, a potent inhibitor of pituitary activity, results in increased secretion of corticotropin, which in turn leads to adrenocortical hyperplasia and overproduction of adrenal androgens and other intermediary metabolites.

Another form of this disease is associated with hypertension. The defect appears to be a deficiency of a second adrenal cortical enzyme, "11-hydroxylase." In this disorder there is, in addition to the deficiency of hydrocortisone, an overproduction of desoxycorti-

costerone, to which the hypertension has been attributed.

A third form of this disorder is associated with a defect in electrolyte regulation, and patients are referred to as "salt-losers." The cause for this form of the disease is not definitely established (see p. 1188).

Administration of hydrocortisone or one of its analogues inhibits the production of corticotropin, which in turn results in reduced production of androgens and other abnormal intermediary compounds of the adrenal cortex. The salt-losing form of this disorder is alleviated by administration of sodium chloride, desoxycorticosterone and hydrocortisone (p. 1189).

Congenital adrenal hyperplasia (p. 238) is inherited as a recessive trait. Parents who have one affected child have one out of four chances of having another affected child with each subsequent pregnancy. It seems that the three forms of the disorder mentioned above are genetically specific. If one form occurs in a family, subsequently affected infants will have the same disorder. The defect in steroidogenesis varies in degree and is often not complete, a fact which accounts for the spectrum of clinical manifestations described in subsequent sections.

**Clinical Manifestations.** In the *male* the main clinical manifestations are those of premature isosexual development, namely, early signs of masculinization such as enlargement of the penis, scrotum and prostate, appearance of pubic hair and development of acne and of a deep voice (Fig. 344). There is accelerated linear growth, the muscles are well developed, and the bone age is advanced for the chronologic age (infant Hercules; macrogenitosomia praecox).

The infant usually appears normal at birth, but signs of sexual and somatic precocity may appear within the first half-year of life or more gradually with sexual precocity not developing until four or five years of age or later (Fig. 344). Owing to premature closure of the epiphyses, growth stops relatively early, and the result is stunted stature.

In congenital adrenal hyperplasia the penis is large and the testes normal, so that they appear relatively small in size. In contrast, both the penis and the testes are enlarged in sexual precocity of hypothalamic origin. Since ectopic adrenocortical cells are occasionally present in the testes, they may, in adrenal hyperplasia, become hyperplastic just as the adrenal glands do and produce enlargement of the testes. In such instances the

patient may be suspected of having true precocious puberty, which, however, does not develop, since spermatogenesis does not take place. The mental development of affected children is usually normal, but the abnormal physical development may result in behavior problems.

The small percentage of patients who have the second type of defective steroidogenesis have severe hypertension in addition to the clinical features described above. A larger number of patients are "salt-losers" (the third type); symptoms of adrenal insufficiency develop early in life (see p. 1188). Hypoglycemic manifestations, secondary to the deficiency of hydrocortisone, are rare.

In the *female*, congenital adrenal hyper-

plasia results in symptoms of heterosexual pseudoprecocity. Since the disorder of steroidogenesis begins early in fetal life, there are almost always evidences of some degree of masculinization of the female fetus manifest at birth by enlargement of the clitoris and variable degrees of labial fusion. These patients are known as female pseudohermaphrodites (Fig. 345).

The clitoris may be so enlarged that it resembles a penis, and, since the urethra opens below this organ, a mistaken diagnosis of hypospadias and cryptorchidism is often made. The vagina has a common opening with the urethra (urogenital sinus). The internal genital organs are those of a normal female.

FIG. 345. Three female pseudohermaphrodites with untreated congenital adrenal hyperplasia. Note the clitoral enlargement and labioscrotal fusion with formation of a urogenital sinus. A, External genitalia of an infant 10 days of age, who was erroneously diagnosed as a cryptorchid, hypospadiac male. Although she was asymptomatic, she weighed 1 pound less than birth weight and was found to be a "salt-loser." B, External genitalia of a 6-year-old girl who was considered normal until 2 years of age, when clitoral enlargement was first noted. Increasing growth of the clitoris and appearance of pubic hair at 5 years of age led to the proper diagnosis. C, External genitalia of a 4-year-old girl with clitoral enlargement from birth and growth of pubic hair beginning at 3 years. All 3 patients showed elevated urinary 17-ketosteroids and pregnanetriol, a female chromosomal sex pattern, a normal vagina on vaginogram and prompt suppression of cortical adrenal activity with cortisone.

After birth the masculinization progresses. Pubic and axillary hair develops prematurely, and acne appears on the face, neck and chest. The voice assumes a masculine quality. These girls are tall for their age, show good muscular development and, in general, have the body build of a boy. Ossification is advanced for their age. Although the internal genitals are female, breast development and menstruation never occur unless the excessive production of androgens is suppressed by adequate treatment.

Hypertension, salt-losing symptoms and hypoglycemia may occur as in the male.

#### CONGENITAL ADRENAL HYPERPLASIA WITH DISTURBED ELECTROLYTE REGULATION

(MIXED ADRENAL CORTICAL DISEASE,  
"SALT-LOSERS")

Addisonian-like symptoms are seen in approximately one third of all infants with congenital adrenal hyperplasia. The diagnosis is being established more frequently in females than in males. This sex predilection may be only apparent and the result of easier diagnosis of the female pseudohermaphrodite early in life. Because of the absence of external genital changes in the male, the symptoms of adrenal insufficiency are often not recognized, particularly when an adrenal crisis simulates a gastrointestinal disorder.

Anorexia, vomiting, diarrhea, loss of weight and extreme dehydration are the outstanding manifestations. Anuria, tachycardia and cyanosis may develop. Restriction of fluid and salt intake results in sudden collapse and death, often preceded by convulsions. Without specific treatment death occurs within a few days or weeks after the onset of symptoms, which begin during the first month of life in more than 90 per cent of affected infants.

The clinical manifestations have frequently led to the diagnosis of intestinal obstruction, pyloric stenosis or a diarrheal disturbance. Instances have been reported in which the presenting problem was a disturbance in cardiac rate and rhythm, suggesting congenital heart disease.

The reason for salt-losing symptoms in some of these patients is not known. Both normal and low levels of the salt-retaining hormone, aldosterone, have been reported. It has also been suggested that these patients secrete a "salt-losing" hormone, but no such substance has thus far been isolated. The

difference between the "salt-loser" and the patient without an electrolyte disturbance may be due to quantitative differences of the underlying enzymatic defect of hydrocortisone synthesis.

**Laboratory Data.** All patients with virilizing adrenal hyperplasia have increased values of urinary 17-ketosteroids for their age. Young infants may excrete as much as 10 mg. in a twenty-four-hour period, and older patients as much as 80 mg. or more. Pregnanetriol, the metabolite of 17-hydroxyprogesterone, is also present in large amounts in the urine of these patients. Blood and urine levels of hydrocortisone are usually low and fail to increase after administration of corticotropin. The circulating eosinophils are, as a rule, increased, and eosinopenia does not follow administration of corticotropin.

Female pseudohermaphrodites with this disorder always have a female sex chromatin pattern. Roentgenographs taken after injection of contrast medium into the urogenital sinus may demonstrate the vagina and uterus. Osseous maturation is advanced, the degree depending on the severity of the disorder and the age of the patient before treatment.

"Salt-losers" have low concentrations of serum sodium and chloride and elevated levels of serum potassium and nonprotein nitrogen. Elevation of the serum potassium may be responsible for abnormal electrocardiographic tracings.

**Differential Diagnosis.** It is important to differentiate congenital adrenal hyperplasia from a virilizing adrenocortical tumor, since treatment of the former is medical and that of the latter is surgical. Females with congenital adrenal hyperplasia offer little difficulty in differential diagnosis because of the presence of a urogenital sinus and enlarged clitoris at birth. In males with congenital adrenal hyperplasia, virilization may not become apparent for several years after birth, thus making differentiation from an adrenal tumor more difficult. A history of congenital adrenal hyperplasia in siblings or the development of Addisonian-like symptoms favors the diagnosis of adrenal hyperplasia. Whenever postnatal virilization occurs under the age of ten years, the presence of a tumor should be strongly suspected; it may be palpable or suggested by displacement of the adjacent kidney as demonstrated by pyelography.

Although the urinary 17-ketosteroid excretion is elevated in both conditions, high values favor the diagnosis of a neoplasm. Large amounts of urinary pregnanetriol are highly

suggestive of adrenal hyperplasia. A therapeutic test with a corticosteroid is one of the most valuable differential procedures, since cortisone quickly suppresses excretion of urinary 17-ketosteroids in patients with congenital adrenal hyperplasia, but not in those with a virilizing tumor. Cortisone, by inhibiting secretion of corticotropin, reduces the abnormal stimulation of the adrenals in patients with hyperplasia, whereas adrenal cortical tumors are not subject to pituitary regulation.

In males an interstitial cell tumor of the testis and true precocious puberty must also be considered. In true precocious puberty gonadotropins may be present in the urine, the urinary 17-ketosteroid level is never above normal adult values, pregnanetriol is not found in the urine, the testes are usually well developed, and interstitial cells may be seen in biopsy specimens. In virilizing adrenal hyperplasia urinary assays are negative for gonadotropins, and abnormal levels of pregnanetriol are found. Urinary levels of 17-ketosteroids are often higher than in normal adults. Biopsy of the testis shows a failure of the interstitial cells to develop. Urinary estrogens are increased in both males and females with virilizing adrenal hyperplasia.

**Treatment.** Cortisone and hydrocortisone are equally effective in inhibiting excessive production of adrenal androgens in patients with adrenal hyperplasia. Intramuscular administration is preferable initially because the results are more predictable. During the first week of treatment 100 mg. of cortisone per day are given intramuscularly to children over six years of age, 50 mg. daily to children between two and six years of age, and 25 mg. daily to children under two years of age.

The urinary excretion of 17-ketosteroids should be used as a guide for determination of the dose. Careful measurements of growth are important in determining the adequacy of dosage, since restoration of normal physical and skeletal growth is a prime objective of treatment. The maintenance dose of cortisone may be administered orally. Fifty to 75 mg. daily for children and 20 mg. daily for infants, given in two or three divided doses, are usually adequate. Such doses suppress excessive androgen secretion without producing undesirable effects. The analogues of cortisone, such as prednisone, are effective in suppressing adrenal androgens, but seem to have no advantage over the parent compounds.

Patients who have disturbance of electro-

lyte regulation ("salt-losers") must be treated with a high salt intake and desoxycorticosterone acetate in addition to cortisone. For adequate replacement therapy of dehydrated infants as much as 4 to 8 gm. of sodium chloride may be required for the first twenty-four hours. For maintenance 2 to 6 gm. of salt per day should be added to the diet and intramuscular injection of 2 to 5 mg. of DOCA should be given daily. Pellets of DOCA may be implanted after the maintenance dose has been determined, or a long-acting form of DOCA may be injected monthly (p. 1185).

#### VIRILIZING ADRENOCORTICAL TUMOR

Tumors of the adrenal cortex result in masculinization in girls and pseudoprecocity in boys. In males the symptoms are usually the same as those occurring with congenital adrenal hyperplasia. It is virtually impossible to differentiate the two conditions on clinical grounds. In females virilizing tumors of the adrenal cause masculinization of a previously normal female, whereas congenital adrenal hyperplasia is almost always associated with genital abnormalities at birth (p. 1187). However, there have been a few instances of adrenal hyperplasia in which virilization had its onset postnatally. The differential diagnosis of virilizing adrenal hyperplasia and adrenal cortical tumor is discussed on page 1188.

The *treatment* is surgical; a transperitoneal approach is usually recommended. Some of these neoplasms are highly malignant and metastasize widely, but cure with regression of the masculinizing features may follow removal of less malignant encapsulated tumors.

A neoplasm of one adrenal may be responsible for atrophy of the contralateral one, owing to excessive production of cortical hormones by the tumor and suppression of the normal gland. Consequently adrenal insufficiency may follow surgical removal of the tumor. This situation can be avoided by giving 100 mg. of cortisone daily, starting on the day of operation and continuing for three or four days postoperatively. It may also be necessary to give corticotropin concurrently with cortisone to reactivate the atrophied gland. Adequate quantities of water, sodium chloride and glucose must also be provided.

#### CUSHING'S SYNDROME

The clinical pattern of Cushing's syndrome is the result of hyperfunction of the adrenal

cortex. When Harvey Cushing described the entity in 1932, he thought it was caused by a basophilic adenoma of the pituitary. In many instances such an adenoma cannot be found at necropsy, and there is evidence that the changes in the pituitary may be secondary to prolonged elevation of corticosteroid levels. Prolonged administration of corticotropin or hydrocortisone or its analogues results in a clinical pattern similar to the spontaneous disorder. Whether Cushing's syndrome is primarily a pituitary, adrenal or hypothalamic disturbance is uncertain.

Cushing's syndrome is most common in young adults and is rare in children; adrenal cortical carcinoma is the main cause in infants and children under ten years of age. Bilateral adrenal hyperplasia is an especially rare cause in children, as is benign adrenal cortical adenoma. An excess of hydrocortisone is essential for the development of this syndrome, although there is usually a mixed form of hypercorticism. Thus, in addition to overproduction of the carbohydrate-regulating hormone, there may be increased amounts of androgens and estrogens. According to the prevalence of a particular hormone, the clinical pattern may vary, and intermediate forms between the adrenogenital and Cushing's syndromes may be manifest.

**Clinical Manifestations.** Symptoms may begin in the neonatal period or any time thereafter. In this form of adrenocortical hyperfunction, obesity of the "buffalo type" and hypertension are outstanding symptoms. The characteristic appearance of these patients is determined by the accumulation of fat on the cheeks, chin and upper parts of the trunk, but sometimes there is a relative lack of fat on the extremities. In spite of their monstrous appearance, such patients are not much above average weight, and they are frequently stunted in growth. There is hypertrichosis on the face, trunk and in the pubic region. The skin appears plethoric, and the cheeks, in particular, are intensely red. Acne is a frequent manifestation even in very young children, but purplish striae on the hips, abdomen and thighs are seen mainly in older children. The voice becomes deep and coarse. In girls the clitoris is generally, but not invariably, enlarged. Sometimes the breasts develop precociously and menstruation begins at an early age. Thus signs of abnormal masculinization and feminization may be seen simultaneously in such girls. In boys the external genitals appear

normal. The blood pressure is elevated, the heart often enlarged, and cerebral hemorrhage may occur. The mentality is initially normal, but as the disease progresses the children frequently become listless, apathetic and dull.

**Laboratory Data.** The red blood cell count and the hemoglobin level are usually in the range of high normal values and there is usually an eosinopenia. The blood sugar level may be normal or high, and there may be glycosuria. The plasma electrolyte pattern is sometimes disturbed, and high concentrations of sodium and bicarbonate and a decrease in potassium may be present. Patients with Cushing's syndrome excrete increased amounts of 17-hydroxycorticosteroids in the urine. These levels may fluctuate from day to day, and repeated determinations may be required to establish the diagnosis. The urinary output of 17-ketosteroids may also be increased. Ossification may be normal or advanced for the patient's age, and there may be osteoporosis with spontaneous fractures.

**Treatment.** All children with Cushing's syndrome should be surgically explored to rule out a tumor. If an adrenal tumor is present, excellent therapeutic results can be achieved by its removal. Adrenal cortical carcinomas frequently metastasize, especially to the liver and the lungs, and the prognosis may be unfavorable in spite of their removal. In instances of a hormone-producing tumor the contralateral adrenal is atrophic, and replacement therapy with cortisone and adrenal stimulation with corticotropin are important adjuvants in the preoperative and postoperative management of the patient. Benign cortical adenomas causing Cushing's syndrome are occasionally bilateral. In such cases the treatment of choice is subtotal adrenalectomy. It is usually necessary to remove 90 per cent of the adrenal cortex to obtain a permanent remission.

#### PRIMARY ALDOSTERONISM

Excessive secretion of aldosterone as a primary disorder of the adrenal cortex due to hyperplasia or a tumor is known as primary aldosteronism. This condition is to be distinguished from that of increased levels of aldosterone seen in many common disorders such as nephrosis, congestive cardiac failure and cirrhosis of the liver and during dietary restriction of sodium leading to secondary aldosteronism. Conn (1955) was the first to recognize the syndrome of excessive aldoster-

onism in a patient, who was subsequently found to have elevated levels of urinary aldosterone. Removal of an adrenal cortical adenoma resulted in spectacular clinical improvement.

**Clinical Manifestations.** The patient has episodes of muscular weakness simulating periodic paralysis. Polyuria, polydipsia, inability to concentrate urine and hypertension are common, and intermittent paresthesias and tetany may be present. The majority of patients do not have edema. There is no evidence of Cushing's syndrome.

The urine is persistently alkaline, and there is mild proteinuria, and a low specific gravity unresponsive to Pitressin. The serum pH and carbon dioxide content and sodium concentration are elevated, and potassium level is decreased. Serum calcium levels, urinary 17-ketosteroids and 17-hydroxycorticoids are normal, but urinary aldosterone levels are elevated. The severe muscular weakness is the result of the low serum levels of potassium. The urinary findings are attributed to "clear-cell nephrosis," a lesion characteristic of chronic hypokalemia.

In the majority of reported instances a benign adrenal cortical adenoma has been found, but a few instances of adrenocortical carcinoma and of bilateral adrenal hyperplasia have also been reported. Removal of the tumor or subtotal adrenalectomy in instances of hyperplasia results in disappearance of the clinical and biochemical abnormalities.

Thus far there have been only three or four instances of this disorder reported in children or adolescents, all of which have had bilateral adrenal hyperplasia. One child with polydipsia and polyuria since early childhood also had moderate growth failure.

#### FEMINIZING ADRENAL TUMORS

Adrenal carcinoma as a cause of gynecomastia has been reported in thirty-five males, but only one of these was a child. Gynecomastia developed during infancy, and the breasts were well developed at two years of age. Growth and development were otherwise normal. At five years of age, after removal of an encapsulated adenoma of the adrenal cortex, there was a gradual decrease in the size of the breasts.

There has been a report of a 5½-year-old girl with isosexual precocity caused by an adrenocortical neoplasm. There was no clinical evidence of Cushing's syndrome or of virilism. An abnormally elevated level of urinary 17-ketosteroids led to the diagnosis.

#### PHEOCHROMOCYTOMA

Several types of tumors are derived from the cells of the adrenal medulla, but only one of them consists of tissue with an internal secretion. These tumors, termed "pheochromocytomas," consist of chromaffin cells which produce large amounts of epinephrine and norepinephrine. Their size varies from a centimeter to about 10 cm. in diameter; they are found more often on the right side than on the left. Less than 5 per cent of the reported cases have been in children. In about 25 per cent of affected children there are bilateral tumors, and in about 15 per cent active tumors have been found outside the adrenal gland. In some instances these tumors occur both in the adrenal and in an extra-adrenal site in the same patient. Pheochromocytomas may occur in more than one member of a family, and in such instances the tumors are usually bilateral. Other neural disorders such as neurofibroma and aganglionic megacolon have been reported in association with these tumors.

**Clinical Manifestations.** These are due to the excess of circulating epinephrine and norepinephrine. The variability of the clinical picture in different patients is explained on the basis of the varying proportions of these two substances excreted. All patients have hypertension at some time. The hypertension may be paroxysmal, a feature which has been thought to be pathognomonic. However, most often the hypertension is sustained, and this is especially so in children. When there are paroxysms of hypertension, the attacks are usually infrequent at first, but become more frequent and eventually may be replaced by a continuous hypertensive state. Between attacks of hypertension the patient may be free of symptoms. During attacks the patient complains of headache and palpitation, and pallor, vomiting and sweating are noticed. In severe cases precordial pains radiate into the arms, and pulmonary edema and cardiac and hepatic enlargement may develop. The child has a good appetite, but does not gain weight, and severe cachexia may develop. Polyuria and polydipsia can be sufficiently severe to suggest diabetes insipidus. Growth failure may be striking. The systolic blood pressure may range from 180 to 260 systolic and 120 to 210 diastolic, and the heart may be enlarged. Ophthalmoscopic examination may reveal papilledema, hemorrhages, exudate and arterial constriction.

**Laboratory Data.** The urine contains al-

bumin, a few casts and occasionally glucose. In many instances the basal metabolic rate may be as high as plus 50 or 60.

A variety of drugs may be used diagnostically, but the two most useful ones are histamine and phentolamine (Regitine). If the hypertension is paroxysmal, histamine administered intravenously stimulates release of epinephrine and norepinephrine, thus provoking an attack similar to those occurring spontaneously. When the hypertension is continuous, Regitine may be used as an adrenergic agent. Three to 5 mg. of this substance administered fairly rapidly by the intravenous route will result in a prompt fall of more than 35 mm. of systolic pressure and of 25 mm. of diastolic pressure if a pheochromocytoma is present. Falsely positive results may be obtained if the patient is taking sedatives or narcotic drugs, and falsely negative ones in patients taking antihypertensive drugs.

The most direct and specific test for the detection of pheochromocytomas is the measurement of urinary excretion or blood levels of catechol amines. Norepinephrine is increased in the urine in all patients; epinephrine is not invariably increased. There is a direct relation between the proportion of these substances in the tumor and in the urine.

**Differential Diagnosis.** The usual causes of hypertension in children must be considered, such as renal disease, coarctation of the aorta, acrodynia, hyperthyroidism, Cushing's syndrome, congenital adrenal hyperplasia and essential hypertension. If the hypertension is paroxysmal, the diagnosis of familial autonomic dysfunction must be ruled out; a number of children with this entity have been explored for pheochromocytoma. Neuroblastomas occasionally produce hypertension and increased excretion of catechol amines.

**Treatment.** Localization of the tumor is often difficult; occasionally it can be discovered by palpation, and in some instances massage of one side produces paroxysms of hypertension. Pyelography, presacral injection of oxygen or, preferably, of pure carbon dioxide, or aortography may reveal the location of the tumor, but often it is demonstrated only by surgical exploration. Removal of the tumor has resulted in cures. The operation is not without danger, because an extreme rise of blood pressure may result from massive discharge of hormone during operative manipulation. Another danger is that of shock from a precipitous drop of blood pressure during operation or within the first forty-eight postoperative hours. These dangers can now

be coped with by the use of Regitine before and during operation to prevent hypertensive crises and of norepinephrine to prevent shock. Utmost vigilance is required postoperatively. The urinary excretion of catechol amines should be determined after operation as a measure of the completeness of the surgical procedure.

## DISORDERS OF THE GONADS

The endocrine function of the testes is attributed to the male sex hormone, testosterone, a product of the interstitial cells of Leydig. This hormone has been extracted and isolated from the testes and can be obtained in crystalline form. Little is known about the endocrine role of the testes during childhood; though such a function cannot be denied *a priori*, there is little proof to substantiate its existence. Signs of castration and testicular failure do not become manifest before puberty. Testicular androgens begin to appear about twelve years of age and act by inducing growth of the penis and development of male secondary sex characters. Spermatogenesis begins about two or three years later. The Leydig cells and the production of their hormone are stimulated by the pituitary interstitial cell-stimulating hormone; spermatogenesis is influenced by the pituitary follicle-stimulating hormone.

The mature ovaries produce two types of hormones, the estrogens and progesterone. Several natural estrogens have been isolated: estrone, estriol and alpha estradiol. The last is the most potent of the natural estrogens and may be the true follicular hormone. Stilbestrol, which is active when administered

orally, is a synthetic compound with estrogenic effects. Estrogens stimulate growth of the uterus, vagina, mammary glands and other female secondary sex characters. Progesterone is a product of the corpus luteum. The female hormones are secreted in periodic cycles, which last in the human being about twenty-eight days. During the first half of the cycle the follicle matures until ovulation occurs in the middle of the intermenstrual period. During this phase of the cycle the estrogens induce proliferation of the uterine mucosa and of the mammary duct system. The secretion of estrogens reaches a peak at the time of ovulation and continues at a lower level during the second (luteal) phase of the cycle. After ovulation a corpus luteum is formed, which produces progesterone. Progesterone inhibits further proliferation of the endometrium, induces secretory activity of its cells, and prepares it for nidation of the ovum. It also develops the alveolar system of the mammary gland. In the absence of a fertilized ovum the progestational uterine endometrium degenerates. The products of degeneration are expelled, with blood and uterine secretions, in the process of menstruation.

The onset of menstruation, the menarche,

is observed most frequently between the ages of twelve and thirteen years. There is, however, a wide range of physiologic variation between eleven and sixteen years. Menarche beyond this range is not necessarily abnormal, but a thorough examination should be made to rule out pathologic processes. Irregularities of cycles are frequent during the first year or two after the menarche, and during this time ovulation does not usually occur. Cramps are associated with ovulatory cycles only.

The normal and pathologic activities of the sex glands are reflected to a certain extent by hormonal substances excreted in the urine. The excreted sex hormones also permit certain conclusions about the functions of the pituitary and adrenal glands. The gonadotropic follicle-stimulating hormone (FSH) and the estrogens are estimated by biologic methods, the androgens (17-ketosteroids) by colorimetric methods.

The gonads are stimulated in both boys and girls by the anterior pituitary. This stimulation becomes manifest at puberty. Only minute amounts of FSH are secreted in both sexes before puberty. In girls FSH can be detected in the urine frequently in the eleventh year of life and usually at least one year before the first menses. In boys this hormone does not appear in measur-

able amounts before the age of thirteen years. These findings are in agreement with the fact that, in general, somatic signs of maturation are seen earlier in females than in males.

Boys as well as girls secrete small but fairly constant amounts of estrogens until the age of seven years (Fig. 346); about that time the excretion of these substances begins to increase in both sexes, but there is little difference in their respective values until the age of eleven years. Then girls show an augmented rate of excretion of estrogens, while that of boys undergoes little change. At the same time cyclic changes of excretion appear in girls. The values charted in Figure 346 represent average monthly excretion rates which deviate from the various daily excretion levels. A single determination of urinary estrogens does not represent a measure of a girl's average excretion, since the values vary a great deal during every cycle. These cyclic variations precede the appearance of secondary sex characters and the menarche. Progesterone is converted into pregnanediol and excreted in the urine.

The excretion levels of 17-ketosteroids in both sexes during childhood and adolescence are indicated in Figure 347. The amounts excreted are less than 1 mg. daily before the

FIG. 346. Excretion of estrogens at different ages. (Adapted from Nathanson, Towne and Aub. *Endocrinology*, Vol. 28.)

FIG. 347. Excretion of 17-ketosteroids in normal persons. The black dots indicate values for boys; the circles, for girls. (Talbot and others: *Am. J. Dis. Child.*, Vol. 65.)

age of eight years, but there is a decided rise between the ages of eight and eighteen years. There is no striking difference in the androgen excretion of boys and girls during childhood, but men show a higher excretion rate than women. The urinary 17-ketosteroids of the female are chiefly of adrenal origin; those of the male are of adrenal and testicular derivation. There are no great daily variations in rates of excretion.

The fact that boys and girls secrete about equal amounts of androgens and estrogens suggests that these hormones are not derived

from the gonads in early childhood. It seems more likely that they are derived, at least in part, from the adrenal cortex. The greater output of sex hormones at puberty parallels the development of the gonads and secondary sex characters so closely that it seems justified to attribute this increase to gonadal function. In various forms of hypogonadism urinary excretion of the sex hormones remains low. Under pathologic conditions high values of androgens and estrogens in the urine may be due to hyperfunction of the gonads or of the adrenal cortex.

## HYPOFUNCTION OF THE TESTES

Testicular hypofunction may be due to primary hypogonadism, to dysfunction of other glands of internal secretion (secondary hypogonadism) or to debilitating disease. After puberty, spermatozoa are formed in the seminiferous tubules of the testes. These organs may also be considered endocrine glands, since the interstitial cells of Leydig produce the male sex hormone, testosterone. These cells are also thought to be the source of estrogen elaborated by the human testis. The spermatogenic and endocrine functions of the testes are to some extent independent of each other. In the absence of spermatogenesis the interstitial cells may continue to function, and

the secondary sex organs and sex characters may remain intact.

### THE EUNUCHOID SYNDROMES

In the absence of the endocrine functions of the testes during puberty and subsequent years, the secondary sex characters fail to develop, resulting in the syndrome of eunuchism. Facial, pubic and axillary hair is scant or absent, and the voice remains high-pitched. The skin of the face becomes wrinkled and assumes a yellowish tinge. The face has a characteristic young-old appearance. There is neither acne nor recession of scalp hair. Fat accumulates in the region of the hips and

buttocks and sometimes also in the breasts and on the abdomen. The epiphysal spaces close late in life. The extremities become long. The span is several inches longer than the height, and the measurement from the symphysis pubis to the soles of the feet is much greater than that from the symphysis pubis to the vertex. These are "eunuchoid proportions." The penis remains small and may be almost obscured by pubic fat.

#### ABSENCE OR ATROPHY OF THE TESTES

The eunuchoid syndrome may be due to congenital absence of the testes (*anorchia*), traumatic or surgical castration, prenatal developmental errors or postnatal infections. In some of these cases the clinical picture may be complicated by associated malformations or defects which are not the result of gonadal hypofunction. This factor explains the great variety of syndromes in which retarded sexual development is a part of the clinical picture. Thus patients with multiple congenital anomalies, including webbed neck and cubitus valgus in association with hypoplasia of the testes, have been described. These patients generally are short in stature and do not have eunuchoid proportions, and the disorder is referred to as *Turner's syndrome*. Atrophy of the testes may follow unskillful manipulation during surgical procedures for correction of cryptorchidism. Signs of hypogonadism become apparent only when both testes are damaged. The eunuchism in these conditions is due to deficiency of androgen resulting from absence of Leydig cells. Testicular biopsies and determination of urinary gonadotropins are valuable diagnostic aids. These patients have excessive gonadotropin excretion because of the absence of inhibitory action of testicular hormone.

**Treatment.** Treatment with gonadotropic extracts is ineffective in primary hypogonadism. Substitution therapy with testosterone preparations must not be begun before puberty and not before the diagnosis of primary hypogonadism has been established. Otherwise, harm may be done to testes that are capable of development and function. Testosterone can be administered by intramuscular injection, orally or by implantation of crystalline pellets. Testosterone propionate is injected intramuscularly three times weekly in doses of 25 mg. until the desired genital growth is obtained. Thereafter the dose is reduced to maintenance levels of 10 mg. three times weekly. Methyl testosterone is used for

oral administration in doses of 20 to 50 mg. daily. Methyl testosterone or testosterone propionate in pellet form is recommended for subcutaneous implantation when prolonged and uniform therapy is attempted.

#### HYPOGONADOTROPIC EUNUCHOIDISM

In this condition there is a deficiency of FSH. This group may be subdivided according to etiology: (1) The deficiency may be secondary to organic lesions in or near the pituitary. Such patients usually show other signs and symptoms of pituitary deficiency, and the extent of testicular failure is roughly proportional to the completeness of the pituitary destruction. (2) More commonly the deficiency of gonadotropic function of the pituitary is a selective one not involving its other tropic hormones. There is no known cause for this disturbance, which is believed to be due to a congenital defect in the pituitary. Familial occurrence of this form of hypogonadism has been recorded. The term "idiopathic eunuchoidism with low FSH" has been applied to this group. In one series of eunuchoids it was estimated that 62 per cent of them fell into this category.

Testicular biopsy reveals typical *histologic changes*, consisting of small tubules without lumens, absence of germ cell proliferation, undifferentiated Sertoli cells and spermatogonia, but no well defined Leydig cells. The histologic picture is that of a prepuberal testis. These patients theoretically should have low levels of both FSH and ICSH. Some of them, however, may show spermatogenesis with deficiency of Leydig cells. It is believed that under such circumstances there is sufficient FSH to stimulate spermatogenesis, but the pituitary secretion of ICSH, which is essential for Leydig cell differentiation and function, is deficient.

Clinically, these patients present the classic stigmata of hypogonadism because of failure to produce androgenic hormone. It has been estimated that 20 to 25 per cent of these cases have cryptorchidism. Urinary assays of gonadotropins after puberty remain at low prepuberal levels.

*Replacement therapy* is indicated. Administration of ICSH in the form of chorionic gonadotropin induces a satisfactory development of secondary sex characters by stimulating the Leydig cells. Reports that spermatogenesis has followed this treatment seem to support the assumption that chorionic gonadotropin stimulates all elements of the

testis. Chorionic gonadotropin in oil and beeswax appears to remain effective longer than the aqueous solution.

Delayed sexual development resulting merely from physiologically slow maturation may be confused with this condition. If therapy is instituted and puberty initiated, it is difficult to assess the parts played by therapy and by endogenous hormones. If, however, the signs of puberty regress after therapy has been stopped, one can attribute the maturation to the gonadotropin injected.

#### KLINEFELTER SYNDROME

(SCLEROSING TUBULAR DEGENERATION, DEFECTIVE TESTES WITH TUBULAR FIBROSIS OR HYALINIZATION, TESTICULAR DYSGENESIS)

This syndrome consists of small testes but otherwise normal external genitals, azoospermia and elevated urinary gonadotropins. In some instances gynecomastia develops at or soon after puberty. Most patients with this disorder undergo normal pubertal changes and attain normal masculinization, but a variable degree of eunuchoidism may occur.

Laboratory studies after puberty show elevated urinary gonadotropin levels and normal or low 17-ketosteroid levels. Testicular biopsies reveal small tubules which are completely or almost completely hyalinized. Occasional tubules contain only Sertoli cells. Leydig cells of variable number and appearance are present.

The recent discovery that a large percentage of patients with Klinefelter's syndrome are chromosomal females came as a startling finding. Warren Nelson proposed the term "true" Klinefelter's syndrome for the chromo-

somal females and "false" Klinefelter's syndrome for the chromosomal males. He established certain histologic criteria by which it is possible to differentiate the two types of the disorder.

These findings have led to reconsideration of the pathogenesis of this disorder, which was formerly thought to begin at puberty. It is now clear that the "true" Klinefelter's syndrome begins early in fetal life. Gonads which should develop into ovaries form structures which appear to be testes, transforming the patient into an apparent male. The disorder may, therefore, be rightfully considered a type of female pseudohermaphroditism. Familial occurrence of the disorder has been reported.

The "false" Klinefelter syndrome, in which the affected person is a genetic male, perhaps may have been caused by a recognized or unrecognized orchitis, although other etiologic factors such as primordial degeneration of the germ cells cannot be ruled out.

These patients appear perfectly normal during childhood, but are detected at puberty because of the appearance of gynecomastia or because of the small size of the testes. The youngest child thus far reported with the syndrome was ten years of age. Determination of chromosomal sex in children with cryptorchidism or hypospadias or with a family history of the disorder could result in diagnosis prior to puberty.

There is no treatment for the gynecomastia or the infertility; gonadotropic hormones are not effective. In patients with some degree of eunuchoidism replacement therapy with androgenic hormone as outlined for patients with absence of the testes (p. 1196) is indicated.

### PSEUDOPRECOXITY RESULTING FROM TUMORS OF THE TESTES

Tumors of the testes which cause sexual pseudoprecocity are derived from the interstitial cells of Leydig. These cells are sparse before puberty, and tumors derived from them are rare. Only twenty-four cases in children have been reported since the first description of the entity in 1895. The interstitial cells are the source of the androgenic hormone which produces the secondary sex characters of the male.

The first changes, enlargement of the penis and development of pubic hair, are seen usually between the ages of four and six years. Later, but long before the usual age

of puberty, axillary and facial hair appears. Hypertrichosis of the chest and extremities may also be present. The boys grow rapidly; they gain in weight and appear muscular and strong. Roentgenograms reveal precocious osseous development. The voice becomes deep. The blood pressure is usually within normal limits. The tumor of the testis as well as the enlarged prostate gland can be palpated. Erections may occur, and the 17-ketosteroids in the urine may be slightly or markedly increased.

Treatment consists in surgical removal of the testis which contains the tumor. In one

instance the tumor was found in the tunica vaginalis completely separate from the testis. A partial disappearance of the signs of precocity has been observed in some patients. Progression of virilization always ceases after

the tumor has been removed. One instance of a bilateral tumor has been recorded, but there is reason to believe that this represented hyperplastic ectopic adrenal tissue. Leydig cell tumors are usually benign.

## GYNECOMASTIA

Gynecomastia, or unusual enlargement of mammary tissue in the male, occurs frequently in adolescent boys. Although the etiology is not definitely known, some of these boys have abnormally high urinary excretion of estrogens for brief periods of time. Spontaneous regression usually occurs within a few months, but the anomaly may persist for several years after puberal development has been completed. Occasionally the gynecomastia precedes other signs of puberal development, and it is not unusual for the two breasts to enlarge at disproportionate rates, at different times, or for only one breast to be involved. Tenderness of the breast is frequent but transitory. No hormonal treatment is necessary. Surgical removal of the breasts is indicated only if the enlargement is marked,

persists for several years and causes serious embarrassment to the patient.

Gynecomastia is also found in a number of pathologic conditions. It may be associated with testicular neoplasms such as interstitial cell tumors or with feminizing adrenal tumors, and in association with Klinefelter's syndrome (*q.v.*). It has also been reported in association with chorioepitheliomas, hepatic disease and paraplegia. Exposure to a surprisingly small amount of estrogens by inhalation, percutaneous absorption or ingestion may be a cause of breast development in prepuberal males; increased pigmentation of the nipple and areola should always suggest this etiology.

An increased amount of fat in the mammary region of obese children is common and is referred to as *pseudogynecomastia*.

## HYPOFUNCTION OF THE OVARIES

Hypofunction of the ovaries may be due to congenital failure of development or to postnatal destruction (primary hypogonadism) or to lack of stimulation by the pituitary (secondary hypogonadism). Many chronic diseases may result in this latter type.

### PRIMARY HYPOGONADISM

#### PREADOLESCENT CASTRATION

Surgical removal of both ovaries results in primary hypogonadism. Fortunately removal of one ovary for lesions such as tumors or torsion has no adverse effect on sexual development. Roentgen therapy over the pelvic area may result in permanent ovarian deficiency; pelvic exposure to 1300 roentgens has resulted in permanent castration of an infant of eighteen months of age.

The endocrine effects of preadolescent castration do not become manifest before puberty, when there is failure of sexual maturation. The external and internal genitalia remain infantile, the breasts do not develop, axillary and pubic hair is scanty, and there is no menarche. Such females grow tall, and the

span and lower measurements are relatively long. Epiphysial closure is delayed. Urinary estrogens are absent; gonadotropins are elevated, and the 17-ketosteroids are usually normal.

### GONADAL DYSGENESIS

(OVARIAN AGENESIS, TURNER'S SYNDROME, BONNEVIE-ULLRICH SYNDROME)

In 1938 Turner described a syndrome consisting of infantilism, webbed neck and cubitus valgus in females. It was subsequently demonstrated that these women had elevated levels of urinary gonadotropins and that the gonads consisted of rudimentary elongated ridges, appearing like whitish streaks. Histologically these gonads resemble ovarian stroma; for this reason the disorder was termed ovarian agenesis. In 1954 Wilkins and Polani demonstrated that a high percentage of the patients with this disorder are chromosomal males. Since the gonads in such instances are actually rudiments of testes, the term "gonadal dysgenesis" was suggested.

**Pathogenesis.** Jost and other workers have shown in animal experiments that functioning fetal testes are necessary for normal male differentiation and that in the absence of fetal testes the organism develops as a female. Castration of normal female fetuses, on the other hand, does not prevent normal female differentiation.

Patients with gonadal dysgenesis are analogous to animals castrated in the fetal stage. Damage to the testes early in fetal life permits persistence of müllerian duct derivatives and feminization of the fetus. This concept has been substantiated by the finding of testicular elements in the nondifferentiated gonads of some patients. Destruction of the fetal ovary does not interfere with female differentiation, so that patients with gonadal dysgenesis cannot be distinguished genetically as male or female by their physical characteristics, but only by their chromosomal sex pattern. Thus it is apparent that patients with Turner's syndrome and a male chromosomal pattern may be considered an extreme example of male pseudohermaphroditism, whereas patients with a female chromosomal pattern may be regarded as having "ovarian agenesis." When the testes are present in early fetal life and degenerate after sex differentiation is complete, anorchia results.

FIG. 348. A 10-day-old infant with enlarged clitoris and labioscrotal fusion who was erroneously considered to be a male. Chromosomal sex was female. A vagina was demonstrated by a vaginogram. Excretion of 17-ketosteroids was less than 0.5 mg. in 24 hours. Exploratory laparotomy and biopsy of both gonads revealed normal ovaries. The mother had received small doses of progesterone during pregnancy. The relation of this therapy to the genital abnormality is not clear.

**Clinical Manifestations.** Patients with this disorder do not develop sexually. The external genitals remain infantile, and the breasts do not develop. The uterus and cervix are small, and untreated patients remain amenorrheic. Growth in height is usually retarded. Though such patients are ordinarily less than 58 inches tall, they surpass in height most pituitary dwarfs. There is no explanation for the stunted growth, since ovarian hypofunction, per se, does not interfere with growth in stature.

Such patients frequently have other congenital defects. Webbed neck, coarctation of the aorta, cubitus valgus, eye defects, congenital lymphedema of the extremities and unexplained hypertension are some of the more common anomalies, but a wide variety of associated skeletal, cardiac and urinary tract anomalies have been reported. Some of the defects are sufficiently serious to be lethal in early infancy. Mental retardation seems to be more frequent than in the general population. If there is enlargement of the clitoris, one speaks of *gonadal dysgenesis with phallic enlargement*. The presence of nests of Leydig cells in the primitive gonads is thought to be responsible for the phallic enlargement.

**Laboratory Data.** The chromosomal sex pattern can be demonstrated in epithelial cells obtained by scraping the oral mucosa; it is male in approximately 80 per cent of persons with gonadal dysgenesis. In patients over ten to thirteen years of age urinary gonadotropins are elevated, but occasionally elevated values have been found in prepuberal children. Mild to moderate retardation of bone age and osteoporosis are common.

**Differential Diagnosis.** All female infants and children with growth failure, especially when associated with congenital anomalies, should be suspected of having gonadal dysgenesis. A male chromosomal sex pattern will establish the diagnosis. Those that show a female chromosomal pattern must be followed up through puberty before the diagnosis can be established, unless pterygium colli and other associated anomalies betray the nature of the disorder. Shortness of stature and sexual infantilism also occur in *pituitary dwarfism*, but pituitary dwarfs have a low rate of excretion or absence of urinary gonadotropins, whereas postpuberal patients with gonadal dysgenesis have elevated levels. This test, of course, is not applicable to prepuberal children. Pituitary dwarfs are much more retarded in growth than children with the syndrome of gonadal dysgenesis. Stocky

FIG. 349. A, A 9-year-old girl with webbed neck, mental retardation and pulmonic stenosis. She had a female chromosomal pattern and elevated gonadotropins. This girl can be considered to have true ovarian agenesis. B, A 14-year-old girl with height-age of an average child of 6 years. Note broad chest and hypoplastic nipples, cubitus valgus, absence of sexual maturation. Chromosomal sex is male.

body build with a broad shieldlike chest and an almost normal epiphysial development are characteristic of gonadal dysgenesis; gracile figure and delayed bone age, of pituitary dwarfism.

**Treatment.** Replacement therapy with estrogens is indicated for primary hypogonadism. This results in development and function of the secondary sex organs, which then simulate those of normal women. In the absence of ova and ovulation, however, reproduction is impossible, and the affected person remains sterile. Treatment may be started at twelve to fourteen years of age. For the first three to nine months 0.5 to 1.0 mg. of stilbestrol is given daily; this results in mammary development and pigmentation of the areola. The uterus grows to adult size, and the vaginal epithelium shows signs of maturation. When these changes are apparent, cyclic treatment is begun. The schedule of treatment recommended by Wilkins consists of 1 mg. of stilbestrol daily for three weeks. During the third week 10 to 30 mg. of anhydrohydroxyprogesterone is also administered daily by mouth. No treatment is given during the fourth week. Menstrual bleeding usually occurs after withdrawal of treatment. At present

there is nothing to be gained by telling the child or the parents of the chromosomal sex pattern if the child is genetically a male. In spite of the male chromosomal sex, the child should be reared as a female. With adequate replacement therapy such children can lead completely normal lives as females except that they are sterile and may be limited by associated congenital anomalies.

## SECONDARY HYPOGONADISM

Hypofunction of the ovaries which results from pituitary and thyroid deficiency can be recognized, as a rule, by associated symptoms. The differential diagnosis between pituitary dwarfism and the syndrome of gonadal dysgenesis has been discussed. It is difficult to distinguish primary hypogonadism from the clinical picture which develops in girls who have a selective deficiency of pituitary gonadotropin. Since such girls are not dwarfed, but tall, and since they have no great delay of ossification and have long extremities, they resemble clinically castrate girls with eunuchoid proportions. The pituitary origin of their sexual immaturity is revealed only by the absence of gonadotropic hormone in the

urine. This hormone is found in excess in primary hypogonadism. Absence of gonadotropic hormone has also been observed in a girl who resembled those with ovarian agenesis. This indicates that some patients with ovarian agenesis may have a coordinated pituitary defect.

In *treatment*, since there are no follicle-

stimulating and luteinizing hormones of pituitary origin available for substitution therapy, one must resort to symptomatic substitution therapy (see therapy of pituitary dwarfs, p. 1153).

Secondary hypogonadism due to thyroid deficiency can be treated successfully with thyroid extract (p. 1167).

## PSEUDOPRECOCITY DUE TO GRANULOSA CELL TUMORS OF THE OVARY

The dominant cell type in feminizing ovarian tumors in children is usually the granulosa cell. There is increasing evidence that histogenetically the granulosa cell and the theca cell are both derived from the ovarian mesenchyma (Novak). This explains the frequent finding of theca cells in granulosa cell tumors and granulosa cells in thecomas. Tumors consisting almost completely of theca cell elements are extremely rare in children.

In spite of variable morphology, granulosa cell tumors produce a similar clinical picture because they secrete estrogens. In the majority of instances they are unilateral and of low malignancy, so that recurrence after removal is infrequent.

As a rule enlargement of the abdomen is the first symptom, and a mass in the lower portion becomes palpable. This is followed by precocious development of isosexual (female) secondary sex characters. The breasts become enlarged, rounded and firm, and the nipples are prominent. Axillary and pubic hair appears. The external genitals resemble those of a normal girl at puberty, and the uterus is

enlarged. At first a white vaginal discharge, followed by irregular bleeding, is noticed. Finally, regular, cyclic menstruation is established. However, ovulation does not occur (pseudoprecocity). As a rule, growth is accelerated and osseous development advanced. Such tumors produce enormous amounts of estrogens, the urinary excretion of which may be increased several thousand times the usual rate. The urinary 17-ketosteroids are only moderately increased.

*Meigs' syndrome* of ascites and hydrothorax has been observed with this tumor in a nine-year-old child. The effusions disappeared after surgical removal of the tumor. Such manifestations should not be confused with metastases, and hence the primary tumor mistakenly considered inoperable.

The tumor should be removed as soon as the diagnosis has been established. The prognosis is good, since metastases are a late manifestation in children and recurrence is rare. Signs of precocious puberty may disappear within a few months after operation. The excretion of urinary estrogens returns to normal values.

## OTHER ENDOCRINE TUMORS OF THE OVARY

(See page 1358.)

### STEIN-LEVENTHAL SYNDROME

This syndrome consists of secondary amenorrhea, a male type of hirsutism, hypoplasia of the uterus and bilaterally enlarged polycystic ovaries. In married women the most frequent complaint is infertility. The disorder is most commonly found in women seventeen to

thirty years of age, but the diagnosis has been established as early as ten years of age. The diagnosis should be considered in adolescent girls with secondary amenorrhea and hirsutism. The enlarged ovaries can often be detected by combined rectal and abdominal palpation. Pneumoperitoneum utilizing carbon dioxide is useful diagnostically. Bilateral wedge resections of the ovaries are indicated.

## HERMAPHRODITISM (INTERSEXUALITY)

In recent years the scope of recognized intersexuality has been increased. In the past hermaphroditism implied a discrepancy between the morphology of the gonads and of the external genitals. Some ambiguity of the external genitals was usually expected. However, the ability to establish the chromosomal sex of the individual has revealed many instances in which it is inconsistent with the apparent sex or even with the gonadal sex. Some hermaphrodites have normal external genitals; only recently have they been recognized as examples of gonadal dysgenesis (p. 1197) or Klinefelter's syndrome.

### CHROMOSOMAL SEX

In 1950 Barr noted that it was possible to identify the sex of an animal by the morphology of the nuclei of the nerve cells of the brain. It was soon found that all somatic cells, including the circulating polymorphonuclear leukocytes, could be used for determination of sex. Identification of sex is based on a mass of sex chromatin in cell nuclei which is present in normal females and absent or insignificant in males. The sex chromatin is typically located on the inner surface of the nuclear membrane. Procedures have been developed for the study of chromosomal sex by fixation and staining of easily available cells such as those of the buccal mucosa or of the vagina. Chromosomal sex is determined at the moment of fertilization and is not influenced by hormones. Its recognition has made possible the diagnosis in early infancy of gonadal dysgenesis without an exploratory laparotomy.

### EMBRYONIC SEXUAL DIFFERENTIATION

In normal differentiation all sexual structures are consistent with the chromosomal sex. Intrauterine castration of rabbit fetuses by Jost showed that differentiation of most secondary characters is not under direct genetic control, but is influenced by secretions of the embryonic gonad. Absence of either ovaries or testes in the embryo results in regression of the wolffian (mesonephric) duct and in the development of the female secondary sex structures (müllerian duct derivatives and the external genitals). It is apparent that

normal male differentiation requires the presence of the fetal testis, whereas female differentiation does not require any gonad. Patients with gonadal dysgenesis who are chromosomal males, but have female external genitals and secondary sex structures, owe this discrepancy to absence of a normal fetal testis (*q.v.*).

One of the last phases of sex differentiation consists in the development of the external genitals. The male external genitals differ from the female in that there is fusion in the midline of the labioscrotal folds and greater development of the phallus. This phase of genital development can be affected, especially in the female, by excess of androgen. Labioscrotal fusion and enlargement of the phallus are seen in infants with adrenal hyperplasia. The increased amounts of androgens from the abnormal fetal adrenal cortex at the stage of external genital development give rise to this abnormality.

### FEMALE PSEUDOHERMAPHRODITISM

The most common disorder of sexual differentiation is female pseudohermaphroditism due to congenital adrenal hyperplasia. It affects female infants who have been masculinized as a result of increased androgenic steroid secretion by the fetal adrenal cortex (pp. 1187, 1188). *Female pseudohermaphroditism not associated with adrenal hyperplasia* has been considered rare. However, in recent years it appears that there has been an increase in this disorder attributable to administration of various steroids to women during pregnancy for the treatment of habitual or threatened abortion. One of the therapeutic agents administered during pregnancy with which the disorder has been repeatedly associated is 17-ethinyltestosterone (Pranone, Progesterol and Lutocylol). Since these substances are widely used, it remains to be explained why they are only occasionally associated with masculinization of the female fetus. Administration of androgens such as 17-methyltestosterone during the first trimester of pregnancy has been reported as the masculinizing agent in some instances. In one instance an arrhenoblastoma in the mother was the cause of female pseudohermaphroditism in her infant. In some instances the masculinizing factor cannot be

identified, an indication that a variety of unrecognized factors may be involved in the etiology.

The appearance of infants with female pseudohermaphroditism at birth is the same as that described for congenital adrenal hyperplasia on page 1187. The principal deviations are phallic enlargement and labioscrotal fusion. Occasionally the fusion is complete and a penile urethra is present. The chromosomal sex is always female. A urethrovaginogram or endoscopic examination reveals a cervix and a uterus. Normal urinary 17-ketosteroids distinguish the nonadrenal cases from those with adrenal hyperplasia.

**Diagnosis and Treatment.** These infants may resemble and be mistaken for cryptorchid, hypospadiac males. The diagnosis of cryptorchidism associated with hypospadias can be made with certainty only by exploration and biopsy of the gonads. Every effort should be made to establish the diagnosis in hermaphroditic infants during the neonatal period so that the child can be reared according to the proper sex. An elevated 17-ketosteroid level in association with the above-described genitals is diagnostic of adrenal hyperplasia. If the 17-ketosteroids are not increased, an exploratory laparotomy and gonadal biopsy are indicated. Irrespective of the external genitals, these infants should be reared as females. The treatment for infants with congenital adrenal hyperplasia is outlined on page 1189. Infants without adrenal hyperplasia require no treatment except for plastic procedures which are best performed between eighteen months and four years of age. When the diagnosis is established in infancy, and there is no attempt to change the adopted sex status after the age of eighteen months to two years, the prognosis is excellent. Female pseudohermaphrodites have a normal potential for fertility.

### MALE PSEUDOHERMAPHRODITISM

All patients in this group are chromosomal males. One type of male pseudohermaphroditism (gonadal dysgenesis) has been described (p. 1198). It may be regarded as the extreme form of male pseudohermaphroditism.

A second group consists of patients with normal female external genitals who are reared as women. The vagina ends blindly, and only rudimentary müllerian duct derivatives are present. At puberty there is normal development of the breasts. The gonads are

testes which consist largely of seminiferous tubules and are located intra-abdominally or in the inguinal canal. Prepuberal children with this disorder have usually been recognized because of inguinal masses which proved to be testes or because of an accidental finding of the testes during herniorrhaphy in apparent females. In adults the amenorrhea may be the only complaint. This disorder has a tendency to re-occur in families.

Psychosexual orientation of such persons is entirely feminine, although they are chromosomal males. The sex of rearing should always be female. It is usually recommended that the testes be removed and that replacement therapy with estrogens be given after puberty.

A third group of male hermaphrodites consists of those who have predominantly masculine or ambiguous external genitals. These persons may or may not have müllerian duct derivatives, and they do not develop breasts, but tend to masculinize at puberty. Sex of rearing has been both male and female. It is highly desirable that "sex" be assigned only after careful study of the patient. The principal determining factor should be the potential for surgical construction of the external genitals even though it may be contradictory to the gonadal or chromosomal sex. Structures contradictory with the "sex" of rearing should be removed. It is not advisable to reverse the sex of rearing of a child with hermaphroditism after the age of two years.

### TRUE HERMAPHRODITISM

True hermaphroditism is a condition in which both ovarian and testicular tissue is present in the same patient. Jones and Scott have accepted sixty cases as proved and divided them into six groups. The clinical features are not characteristic and include those described for all other types of hermaphroditism. The chromosomal sex may be male or female. Definitive diagnosis can be established only by biopsy of both gonads. True hermaphroditism must be considered in the differential diagnosis of all types of intersexuality except congenital adrenal hyperplasia. Treatment is the same as described for male pseudohermaphroditism.

# Metabolic Disorders

## DIABETES MELLITUS

Diabetes mellitus is a disorder of carbohydrate metabolism characterized by hyperglycemia and glycosuria and associated with abnormal metabolism of fat and protein. In the untreated state there is loss of weight and the development of acidosis.

**Incidence.** The incidence of diabetes in childhood has been estimated to be from 5 to 8 per cent of all cases. There is no strong sex factor, although in some series there is a slight preponderance of females.

**Etiology.** Diabetes mellitus is a hereditary disease and in most instances appears to be transmitted as a recessive character. Evaluation of the genetic pattern is complicated by the variability in the clinical expression of the disease. This situation is pointed up by such factors as (1) the wide age range in which the disease may become manifest (infancy to old age), (2) the variability in clinical severity, some cases being clinically inapparent, perhaps at times indefinitely, and (3) the similarity of clinical patterns in newborn infants of diabetic mothers and prediabetic mothers. Diabetes occurs more frequently in both members of identical twins than in those who are not identical.

Whether certain factors may precipitate manifest disease in the potentially diabetic person is of some importance. It is thought that obesity may be such a factor in the adult, but there is no evidence that either overindulgence in eating or obesity is related to the onset of diabetes in childhood.

The relationship of endocrine glands other than the pancreas to the metabolism of carbohydrates is recognized but incompletely understood. Diabetes can be produced in the experimental animal by the appropriate injection of anterior pituitary extract, and diabetic-type glucose tolerance curves can be produced more often in persons of a diabetic kinship than in those of a nondiabetic one. Hyperglycemia is occasionally associated with such endocrine disturbances as acromegaly,

Cushing's syndrome, hyperthyroidism and pheochromocytomas. These disturbances of carbohydrate metabolism usually disappear if the endocrine disturbance is controlled.

Attempts have been made to incriminate infection as a cause of diabetes. The evidence does not support such a relationship; however, it does indicate that acute infection may be a frequent "trigger mechanism" activating a latent state of diabetes mellitus in children.

**Pathologic Physiology.** Diabetes mellitus is the manifestation of a deficiency of insulin. The metabolic pattern which evolves from this deficiency is far more complicated than simple interference in the utilization of sugar, and many aspects of the total disrupted metabolic pattern are not understood. What follows is merely an attempt to enumerate some of the metabolic defects which contribute to the clinical expressions of this disease.

Most significant is the fact that, when there is insufficient insulin or when its effect is inhibited, a sequence of events is set up which terminates in diabetic acidosis, coma and death. In the absence of an adequate supply of insulin there is (1) impaired glycogen formation in the liver and in the muscles, (2) increased glycogenolysis, and (3) deficient utilization of glucose by the peripheral tissues. As a result there is hyperglycemia, which, when it exceeds the renal threshold, is responsible for glycosuria. The diuresis initiated by the hyperglycemia accounts not only for the excretion of excess glucose, but also for excessive losses of electrolytes and water.

The loss of water and electrolytes is from both intracellular and extracellular compartments. The breakdown of tissue and the consequent freeing of potassium and phosphates result in abnormally high levels of these electrolytes in the blood at a time when the total body stores of them are being significantly depleted. The loss of body water results in hemoconcentration and dehydration, which in turn are responsible for de-

creased renal function. The shift of electrolytes from the intracellular to the extracellular spaces, the hemoconcentration and the renal dysfunction create a state of relative hyponatremia which, except as it is interpreted in the light of the altered physiology, may create a false impression of the body stores.

The tissue breakdown results in part from osmotic forces, in part from tissue catabolism secondary to the inability to use glucose for fuel. Both protein and fat are oxidized at abnormally rapid rates. The increased rate of breakdown of fat in the liver results in overproduction of ketones and in discharge of them into the blood at a rate exceeding the capacity of the peripheral tissues to oxidize them and of the kidneys to excrete them. Ketonuria may occur at blood levels which do not disturb the acid-base equilibrium, but the accumulation of ketone bodies in the blood of the uncontrolled diabetic does become sufficient to be a substantial factor in the development of acidosis. The other factors in the development of acidosis are dehydration, renal dysfunction secondary to anhydremia and loss of fixed base. Late contributory factors are loss of water through the hyperpnea caused by the acidosis and accumulation of lactic acid during cardiac failure.

The specific causes of coma are not apparent, but cerebral cellular activity is probably adversely affected by all the various metabolic derangements. Whether anoxia is a cause or merely an accompaniment is not known, but Kety's observation of diminished cerebral oxygen uptake during coma is one of the strong arguments in favor of the correction of excessively low pH levels early in the course of therapy of diabetic acidosis. Acidosis also inhibits restoration of the disrupted metabolism in the uncontrolled diabetic state in other ways. Guest and his co-workers showed that lowering of the pH and alkali reserve of the body fluids leads to hyperglycemia, hemoconcentration, losses of intracellular labile phosphates and potassium and inhibition of insulin action.

Thus in the uncontrolled diabetic patient there are severe losses of body water and electrolytes, depletion of fixed base, lowering of the plasma carbon dioxide content, a shift of the pH of the blood to the acid side and depletion of the glycogen stores in the liver and muscles.

Therapy, to be rational, must be directed toward restoration of metabolic equilibrium.

**Pathology.** The outstanding feature is the

lack of correlation between the pathologic changes and the severity of the diabetes. In some instances the changes are so slight that their significance is doubtful. There is at times diminution in the size of the pancreas, and a decrease in the number of the islands of Langerhans has been observed. The most characteristic lesion of the islands in children is lymphocytic infiltration, believed to be a response to a pre-existing injury rather than a primary change or cause. Hydropic degeneration may be present, but hyalinization, a common finding in adults whose diabetes was of long duration, is rare in children. Hepatomegaly is not an uncommon finding, and chemical studies reveal a depletion of glycogen. Histologic studies reveal little or no glycogen in the cytoplasm, but deposition of it in the nuclei. Arteriosclerosis and other degenerative changes occur with increasing frequency in young adults after fifteen years of clinical diabetes.

**Clinical Manifestations.** In general the symptoms of diabetes mellitus in children are similar to those in adults. The principal differences are that the onset is likely to be more rapid in children, and the diabetic child at the time of onset is more likely to be underweight in contrast to the frequency of obesity in adults. The chief symptoms are wasting, increased thirst and appetite and polyuria. The symptoms are somewhat more variable than in adults, and not infrequently the onset is so rapid that none of them has been noticed, or their existence is brought out only by leading questions. The child may be brought for medical attention because he has failed to gain weight in spite of a voracious appetite. One of the more frequent evidences of polyuria is bedwetting in a previously trained child. In untreated and long-standing cases dryness of the skin and pruritus are not uncommon, and there may be hypertrichosis. In infants and small children the hair on the body has a soft texture not unlike that of lanugo. Skin infections are common, but the converse—a high incidence of diabetes in association with chronic infections of the skin—is not the case. Intertrigo and secondary skin infections are particularly common about the genital region in small children.

The presenting symptoms are often those of coma or stupor (diabetic acidosis), particularly when there is an existing acute infection or if there has been a recent one. In the precomatose state there is drowsiness, dryness of the skin, flushed cheeks, cherry-red lips, acetone breath, hyperpnea, nausea

and vomiting, abdominal pain and often general body pains. In complete coma the hyperpnea becomes greater (Kussmaul breathing), the eyeballs are soft and sunken, the abdomen is rigid, the pulse is rapid and weak, and the temperature and blood pressure are subnormal.

**Chemical Changes.** The characteristic changes in the nonacidotic state consist in glycosuria, with or without ketonuria, and hyperglycemia. The absence of a fasting hyperglycemia does not rule out the possibility of diabetes mellitus. In rare instances the fasting blood sugar of an infant or young child who has only recently acquired diabetes may not be above the normal level, and a glucose tolerance test will be required to establish the diagnosis. Ketonuria may exist without measurable disturbance of the acid-base equilibrium, and there is no consistent relation between the degree of hyperglycemia and the absence or presence of ketonuria or its degree. Blood sugar levels as high as 800 to 1000 mg. per 100 ml. have been observed without an associated ketonuria in children who have eaten large amounts of carbohydrate. The blood cholesterol and lipid levels may be elevated in untreated diabetics; there does not appear to be a relationship with the duration or the severity of the disease.

With the development of acidosis there is a lowering of the carbon dioxide content of the blood, and a shift of the pH to the acid side. There is often an elevation of the non-protein nitrogen. Albumin and casts are frequently present in the urine at such times, but disappear when the acidosis is corrected.

**Diagnosis.** Children in whom the diagnosis of diabetes mellitus must be considered may be divided into three general categories: (1) those who have a history suggestive of diabetes; (2) those who have a transient or persistent glycosuria; and (3) those who have clinical manifestations of acidosis with or without stupor or coma. In all instances the diagnosis depends upon laboratory data. Glycosuria associated with a fasting hyperglycemia is for practical purposes diagnostic of diabetes mellitus. However, it is necessary to eliminate the rare possibilities of Cushing's syndrome, hyperthyroidism and pheochromocytoma. Transitory glycosuria may be the result of emotional disturbances, of overeating (alimentary glycosuria), of acute infections, of cerebral injuries, of lead poisoning and of the ingestion of certain drugs. Salicylates may be responsible for a reduction of Benedict's solution which may simulate that by sugar.

Renal glycosuria is the result of a lowered renal threshold for sugar, but there is no hyperglycemia, and the glucose tolerance curve is either within or below the usual range. The level of the renal threshold for sugar can be established by the sugar clearance test. It is important to bear in mind that not all urinary sugar is glucose, and steps should be taken to ensure that the unusual instances of pentosuria and galactosemia are not diagnosed as diabetes mellitus.

Whenever sugar is detected in the urine, a blood sugar determination should be obtained. If there is only a small amount of sugar in the urine, a fasting blood level may be obtained the following morning. If, however, there is considerable urinary sugar and/or if acetone is also present, a blood sugar determination should be obtained immediately. If the blood sugar is more than 200 mg. per 100 ml., a tentative diagnosis of diabetes mellitus is justified; if it is under this level, a fasting specimen of blood should be obtained the following morning; if the level is then within the normal range, a glucose tolerance test should be performed. The glucose tolerance test should be reserved for questionable cases; fasting and postprandial blood sugars will usually serve both for diagnosis and for evaluation of treatment.

**Diabetic acidosis** with or without coma must be differentiated from acidosis and/or coma resulting from other causes, such as hypoglycemia, uremia, gastroenteritis, lead poisoning, salicylate poisoning, encephalitis, cerebral hemorrhage and other intracranial lesions. The symptoms previously described aid in differentiation, but the diagnosis must be based on laboratory analyses. Abdominal pain, tenderness, muscular rigidity, vomiting and leukocytosis are commonly present in diabetic acidosis. Though it is possible that acute appendicitis or other intra-abdominal infection may be the inciting cause of diabetic acidosis, it should be recognized that the differential diagnosis cannot be made until the symptoms of acidosis have been relieved. High white blood cell counts may exist in association with diabetic acidosis, and do not in themselves indicate an infection.

**Complications.** Except in cases of long duration or in inadequately treated ones, complications are uncommon. Gangrene is a rare complication, but has been observed even in newborn infants. Stunting of growth, lack of development, failure to develop secondary sexual characteristics, and amenorrhea are seen in children whose diabetes has been un-

controlled over long periods of time. Hepatomegaly, though not a frequent complication, apparently occurs more often in inadequately treated children than in adults. Cataracts may occur at any age, but their incidence increases with duration of the disease; arteriosclerosis is seen with frequency only after the disease has existed for ten to fifteen years. Xanthomatous deposits in the skin occur occasionally in uncontrolled diabetes in association with hyperlipemia. *Necrobiosis lipoidica diabetorum* is an uncommon cutaneous lesion characterized by elevated red papules 1 to 3 mm. in diameter, which eventually develop a yellowish tint. Carotenemia with resultant discoloration of the skin is more frequent in diabetics than in nondiabetics, and apparently is a reflection of hepatic dysfunction in the conversion of the provitamin A, carotene, to vitamin A. In poorly treated diabetic children infections not only are common, but also show less tendency to heal; among the more frequent are dental caries, infections of the respiratory and lower urinary tracts, skin infections and tuberculosis.

Complications associated with the injection of insulin are lipodystrophy (atrophy of the subcutaneous fat), lipomatosis (a lipoma-like swelling) and allergy to insulin. Lipomatosis and possibly also lipodystrophy are the results of repeated injections of insulin into the same area, and perhaps of too superficial injection.

**Course and Prognosis.** Prior to the introduction of insulin in 1922 the life expectancy of diabetic children was only about two years after the onset of the disease. What the expectancy is for the insulin-treated patient is not known, but in recent years the outlook has become less bright than it seemed in the earlier years of the "insulin era." The reason for this apparent change is based primarily upon the relative frequency with which serious degenerative lesions are appearing in young adults who have had diabetes for ten to twenty years. These complications consist principally in arteriosclerosis with hypertension, retinal and lenticular changes and nephropathy, the characteristic lesion being intercapillary glomerulosclerosis (Kimmelstiel-Wilson syndrome). The incidence of complications in persons who have had diabetes for twenty years or more is as high as 85 per cent in a large series (White). The high incidence of vascular degenerative disease constitutes the most important problem in juvenile diabetes. There are those who are inclined to the view that these complications

are manifestations of a phase of diabetes which is not affected by presently available therapy. Some attach causal significance to deviations in clinical control sufficient to result in high blood cholesterol levels and frequent episodes of ketosis and acidosis. There is less agreement about the significance of hyperglycemia, per se, or of adherence to a prescribed diet.

Physical growth and development are related to control of the diabetes. To what extent they are related to a degree of control which approximates normoglycemia is not known. Beal's data on a group of children whose diabetic control was probably well above average show a slight delay in growth in stature, but a tendency to approximate average adult heights after a somewhat prolonged growth period. Some diabetic children whose disease is kept under adequate control are small in stature and continue to remain well below the average physical development of their age group. In such instances deficiency of other endocrine glands has been postulated but not established.

The so-called *Mauriac syndrome*, the underlying problems of which are not understood, consists of dwarfism, hepatomegaly and obesity in association with diabetes mellitus.

Comparatively little difficulty is encountered in management of the average pre-adolescent diabetic child, provided both the child and his family are properly instructed in the technique of diabetic care and assisted in making the necessary psychologic adjustments. The adolescent child, however, has a natural inclination to rebel against authority and restraint, which is often reflected in breaks in diabetic control. At such times both the physician and the parents must take care that they do not lose the confidence and cooperation of the child.

**Treatment.** The aims of treatment are restoration of the diabetic child to average physical status and health, and subsequent maintenance of them. Control of the metabolic aspects of diabetes is merely a means to an end. The child who is not physically and socially able to compete with his colleagues cannot be considered an adequately treated diabetic child.

The essentials of treatment are (1) insulin in an amount adequate to maintain or approximate glycemic equilibrium; (2) a diet adequate for normal growth and activity and sufficient to satisfy the child's appetite; (3) instruction of the child and his parents in the ordinary routine care of diabetes so that

may be satisfactorily managed in the home; and (4) acceptance on the part of the child and his family that he is a "normal" healthy person able to compete with children of his own age.

Treatment may be divided into four phases, depending upon the state of control of the diabetes at the moment: (1) acidosis; (2) postacidotic stage; (3) establishment of glycemie equilibrium; and (4) supervision of the controlled diabetic child.

**Diabetic acidosis.** Diabetic acidosis is a medical emergency requiring constant attention and teamwork among doctor, nurse and laboratory. Recovery from diabetic acidosis is directly related to its duration, its degree, and the state of consciousness of the patient on the one hand and of the quantitative aspects of treatment on the other. When it is not known that the patient is diabetic, the diagnosis can be established only by laboratory means. A sample of blood should be taken immediately for determinations of the blood sugar level and the carbon dioxide-combining power or content, and a specimen of urine should be obtained, by catheterization if necessary, for examination for sugar and acetone.

A plan of fluid and insulin therapy is detailed on page 189. The plan of therapy in our clinic differs in only one feature. For the patient who is in a severe state of acidosis (pH less than 7.1; carbon dioxide less than 6 mEq. per liter) we administer sodium bicarbonate after the initial expansion of the vascular volume with saline solution. This policy is based on clinical experience and on the physiologic considerations stated previously. In comparative observations in children and in animals recovery as based on return of consciousness and ability to take and retain oral feedings has been more rapid when bicarbonate was administered early in therapy. Further, we have not observed any untoward results from such therapy. It should be clearly understood that only enough bicarbonate is given to raise the carbon dioxide level to 10 to 12 mEq. per liter (p. 191).

Potassium is administered relatively early as indicated on page 189. Our usual practice is to add potassium chloride to the glucose-saline solution being administered intravenously in an amount so that its concentration does not exceed 0.15 per cent rather than administering it as a separate solution subcutaneously. This latter method may have advantages.

*Gastric lavage* is invariably beneficial in

the acidotic patient. It will not only avert subsequent vomiting in the majority of instances, but will also shorten the time until fluids and foods can be taken by mouth. After the stomach has been thoroughly emptied of its contents, which often contain digested blood, several grams of sodium bicarbonate in solution may be introduced. The lavage may be delayed until after the parenteral fluid therapy has been started.

**Postacidotic stage.** Parenteral fluid therapy can usually be terminated in less than twenty-four hours. For the next twenty-four to forty-eight hours the child will require special attention. As soon as he is ready to take fluids by mouth, sips of water or chilled ginger ale may be given for a few hours or until it is evident that vomiting or gastric distention is not likely to occur. A soft or liquid diet consisting chiefly of carbohydrate may then be started and given to the child at approximately three-hour intervals during the day hours. Such foods as fruits, fruit juices, skimmed milk, fat-free ice cream, and gelatin desserts are taken well. The insulin dosage during this time is entirely empiric and is based on urine analyses for sugar. It is best to give small doses of regular insulin at frequent intervals rather than large doses at infrequent intervals. Careful check should be maintained at this time to avoid insulin shock or the return to hyperglycemia. After a day or two on this regimen the child should be ready for an average diet.

**Establishment of glycemie equilibrium.** The suggestions made here are also applicable to the child who has not been in acidosis, but is not in satisfactory diabetic control. There are no hard and fast rules, and each child must be regarded as an individual problem for whom a satisfactory diet must be arranged and the insulin dosage determined. No attempt should be made to avoid the use of insulin. Rarely after the initial period of stabilization, insulin may be dispensed with for a time, but in such instances the patient and his parents should be advised that insulin will be required again within a comparatively short time.

**Diet.** There has been a gradual transition in types of diets prescribed for diabetic children. The prescription of low carbohydrate diets has for practical purposes ceased, and the tendency now is to provide a diet which approximates that of the average child and conforms to the family's dietary pattern. Principal differences exist now in whether the diet is measured or is unrestricted ("free

diet"). The so-called free diet is usually restricted to the extent that the children and their parents are cautioned against dietary excesses, especially of "sweets" and food-stuffs of high carbohydrate content. There is no doubt that one of the essentials in the management of the diabetic child is complete acceptance of the disease and its management without the sense of undue restriction or of being "different" from other children. Such an ideal situation is usually not attained; if the use of the "free diet" could be the determining factor in attaining it, its use would be justified. In our experience, however, we have felt that most often both child and parent felt more secure and profited initially from a guided dietary program.

It is our practice to prescribe the initial diet for the child while he is in the hospital. After the first week or so of the insulin adjustment period the child is consulted about his satisfaction with his diet and requested to participate in planning his "home diet" both qualitatively and quantitatively. The method devised by Stare is used, and the child and his mother are given a copy of the "Exchange Lists" (p. 1409). They should know that the diet is not a rigid one, that gross household measures are adequate, and that occasional quantitative deviations are of no great consequence. Though the diet is not an entirely unrestricted one, it can be a self-determined one. The goals of such a plan are (1) to ensure a qualitatively satisfactory intake; (2) to secure an adequate distribution of caloric intake at the various meals; and (3) to teach the child by experience the "self-serving" of meals at a later age. The essentials of an adequate diet are (1) sufficient caloric value for activity and growth; (2) a protein intake not less than 1.5 gm. per pound of body weight for children under three years of age, and 1 gm. per pound for older children; (3) 40 to 50 per cent of the calories as carbohydrate; (4) optimal intake of vitamins and minerals; and (5) participation of the diet by the entire family.

A reasonable distribution of calories can be obtained by the use of one of the following formulas:

	Carbohydrate		Protein		Fat		Cal./Kg.	Cal./Lb.
	Kg.	Lb.	Kg.	Lb.	Kg.	Lb.		
Grams per								
unit of	9	4	3	1.5	2.5	1.5	70	35
body	9	4	2	1.0	2.5	1.5	66	33
weight	7	3.5	3	1.5	2.0	1.0	58	29
	7	3	2	1.0	2.0	1.0	54	25

See page 100 for average caloric requirements at different age levels.

"Stabilization" should be carried out, if at all possible, while the patient is normally active. Even in the hospital the child may be permitted considerable activity. The initial diet should subsequently be adjusted on the basis of the appetite and the growth response (as indicated by the weight curve). If growth is normal and appetite is satisfied, the diet remains as planned; if growth is not proceeding and appetite is not satisfied, the diet is increased; if there is no gain in weight, but the appetite is satisfied, more food is prescribed and more concentrated foods are substituted for relatively bulky ones; or, if the patient is gaining, but the appetite is not satisfied, the bulk of the diet is increased without increasing the caloric value. There is no need to use commercial diabetic foods.

**Insulin.** Insulin is the sine qua non of diabetic therapy. No juvenile diabetic can be treated without it. The principal question is the degree of control of hyperglycemia which is attempted. A few clinicians believe that, except as hyperglycemia is sufficient to cause excess diuresis, it is not harmful; otherwise their only concern is ketosis. Others hold that a reasonable attempt should be made to achieve a normoglycemic status; we subscribe to this goal, but only so far as it can be attained without the occurrence of hypoglycemic attacks, other than as rare occurrences, and without too great dietary rigidity. Practically all children excrete small amounts of sugar daily on this plan.

The sulfonylureas, as orally administered hypoglycemic agents, are being widely used as substitutes for insulin in adults with mild diabetes. To date it is the consensus that they do not provide a reliable replacement for insulin in the treatment of juvenile diabetes. However, the possibility that effective usage of available agents or that more effective ones will be found justifies continued clinical investigation in this aspect of diabetic control.

There are now available at least five different forms of insulin: (1) regular or unmodified insulin; (2) protamine zinc insulin; (3) NPH insulin; (4) globin insulin; and (5) Lente insulin. The effect of unmodified insulin upon the blood sugar is apparent within twenty or thirty minutes after injection and is maintained for six to eight

hours. The effect of protamine insulin is apparent within an hour or so, but its full effect is delayed for about three hours after injection; if sufficiently large doses are injected, its effect may be prolonged for twenty-four hours or more. The actions of Lente, NPH and globin insulins are somewhat between these two: The initial effect is delayed beyond that of unmodified insulin, but is more rapid than that of protamine, and the effect is maintained for a longer period than that of unmodified insulin, but for a shorter period than that of protamine.

However, if sufficient Lente or NPH insulin is administered as the prebreakfast dose, an effect can be secured for twenty-four hours or so. In this respect they are similar to protamine zinc insulin. They have the added advantage that their quicker action will, in many cases, provide sufficient insulin action to avoid significant glycosuria during the day hours, and still maintain nocturnal control without hypoglycemia. More often, however, unmodified insulin will have to be administered along with Lente or NPH insulin to avoid significant diurnal glycosuria if diurnal control without insulin shock is desired. The majority of our diabetic children receive a combination of Lente and unmodified insulin. One of the advantages of Lente and NPH insulin over protamine zinc insulin is that regular insulin can be included in the same syringe without being altered; it thus behaves as if it were a separate injection. Lente insulin contains no protamine, so that the slight possibility of induced allergy to it is eliminated. For infants and children up to four or five years of age unmodified insulin for the prebreakfast and prelunch injections and Lente insulin for the evening injection are preferable.

The insulin dose is estimated from qualitative tests of the urine for sugar. Specimens of urine should be collected four times a day: (1) before breakfast (7 to 8 A.M.), (2) before the noon meal (11:30 A.M. to 12 noon), (3) before the evening meal (5 to 6 P.M.), and (4) before retiring (7 to 9 P.M.). The results of analyses of these specimens will be of greater aid in estimating insulin dosage if the child voids (discarding the specimen) from one-half to one hour before each of the three latter specimens is obtained.

After the first day or two of the postacidotic stage as described above, an average diet is provided, and unmodified (regular) insulin is given before each meal. Individual doses

are usually in the range of 10 to 15 units; estimates can be made from the experience of the preceding days, and adjustments made daily on the basis of the qualitative urine test for sugar in specimens voided about three hours after each meal, as noted above. After two days or so a reasonable estimate of the total daily dose of insulin which is sufficient to effect a reduction in the urinary sugar without causing insulin shock can be made. At this time one may initiate the permanent plan for insulin therapy. It is our practice to give about 75 per cent of the previous day's total dose of insulin as Lente insulin and the remainder as unmodified insulin before breakfast. Subsequent adjustments of the dose of each insulin are made on the basis of the presence or absence of sugar in the urine and/or by the occurrence of insulin shock: The dose of Lente insulin is adjusted so that the urine of the following morning contains little or no sugar and so that the child does not have insulin shock during the night or prebreakfast hours. The dose of the unmodified insulin is estimated on the basis of the urinalyses preceding the noon and evening meals and/or the occurrence of insulin shocks during this portion of the day. Under such a plan an attempt is made to secure an average blood sugar level the following morning and urine tests at noon and in the afternoon which indicate only small amounts of glycosuria. Occasionally, satisfactory glycemic equilibrium is obtained with only Lente insulin, but most often unmodified insulin will also have to be continued in the prebreakfast injection. Rarely is an additional dose of unmodified insulin given before the evening meal to avoid glycosuria during the evening hours. If there is only a transitory spilling of sugar after the evening meal and if, on the following morning, the blood sugar level is within the normal range or the urine does not show sugar, there does not appear to be any need for injection of insulin before the evening meal.

The urine can be made essentially sugar-free within about a week by this regimen. In the majority of instances, however, the dose of insulin at this stage does not represent the child's maintenance dose. During the next three to six weeks it will usually have to be decreased. The need for decreasing it is determined on the basis of blood sugar levels below the normal range or by hypoglycemic shock. A general metabolic adjustment appears to take place gradually, and there is no known

way to shorten this period. There are distinct advantages in keeping the child hospitalized but not inactive for at least the first two or three weeks of the initial adjustment period. The latter part of this period can then be managed in the child's home, provided instruction of the patient and his family has been adequate and careful records of urine analyses for sugar will be kept.

Insulin should be administered subcutaneously, care being taken that it is not injected too near the skin. Definite instruction should be given for changing the site of injection: e.g., successively into the right upper arm, the left upper arm, the left thigh, the right thigh. Each extremity may be used for several weeks without making two injections into the same site, provided a systematic plan is followed. Thus, starting at the inner and upper corner of an area to be used, each succeeding injection is made  $\frac{1}{2}$  inch below the preceding one, and when each vertical line is complete, the site selected is moved outward  $\frac{1}{2}$  inch at the upper level, and injections then proceed downward in a similar vertical manner. Other sites which may be used are the upper part of the buttocks, the back and the abdomen. If signs of induration appear at the sites of injection, these areas should be carefully avoided for several weeks after all evidences of local irritation have disappeared. In case of allergic reactions to insulin, the commercial brand or the type of insulin should be changed. Patients receiving insulin should bathe at least every other day, and sterile technique should be practiced in preparing the needle, syringes, bottle caps and the skin at the site of the injection.

*Among the factors which vary the need for, or utilization of, insulin are diet, physical activity, infection and, to a less extent, growth.* No definite rule can be stated about the possible need for increased insulin with increase in diet or body weight. Many children require gradual increases in insulin dosage up to puberty, and then often further but temporary increases during early adolescence, whereas others do not. Increased dietary intake usually does not require proportionate increase of insulin dosage, often none at all.

Exercise tends to lower the blood sugar level of children receiving otherwise adequate amounts of insulin and may thus initiate insulin shock. Diabetic children should, however, be encouraged to be normally active; so far as possible, exercise should be regulated in quantity and time so that allowance may

be made for it in the adjustment of insulin dosage. The child should be instructed to carry sugar with him at all times and to take it whenever the first symptoms of shock are noted. When it is known that there is to be an increase in physical activity, the dose of insulin for that day can be reduced by an amount determined by experience to be satisfactory.

Infection increases the requirement for insulin and is the most potent factor in initiating acidosis. During mild infections, such as those of the upper respiratory tract, the only treatment required for the diabetic condition is sufficient extra insulin to prevent glycosuria. In more severe infections the fat should be decreased in the diet, extra carbohydrate should be administered if the child's appetite requires it, and additional insulin should be injected as needed. An adequate plan for adjustment of insulin dosage during infection in children receiving a combination of Lente and unmodified insulins is to maintain the quantity of Lente insulin at the previous dose and to add extra unmodified insulin at breakfast, lunch and dinner in amounts estimated from the results of Benedict's test of the urine. It is important to bear in mind that the dose of insulin must be reduced again during convalescence.

*Insulin shock* may result from an overdose of insulin, from reduction in diet or from increase in exercise without a corresponding reduction in insulin. Early symptoms are sudden hunger, weakness, restlessness and nervousness, pallor, sweating, and dilated pupils; if carbohydrate is not administered, there will occur tremor, vertigo, unconsciousness, convulsions and in rare instances even death. In shock from overdose of protamine insulin and to a less extent of Lente and NPH the onset is less abrupt, and the reactions usually, but not always, less severe. Vomiting during and after shock from the long-acting insulins may occur, but it practically never occurs in shock from unmodified insulin. The slower onset of shock from the long-acting insulins, together with the vomiting, may lead to an incorrect diagnosis of diabetic acidosis.

The time of occurrence of hypoglycemic shock after injection of insulin may aid in the differential diagnosis of shock from coma. Shock from unmodified insulin occurs usually three to eight hours after injection, that from Lente, NPH and protamine insulins usually eight to twenty-four hours after injection. If,

however, it is not clear whether unconsciousness is the result of hypoglycemia or diabetic acidosis, 20 to 10 ml. of 20 to 50 per cent glucose should be injected intravenously. If unconsciousness is the result of hypoglycemia, consciousness will be quickly restored, and no harm will be done by the injection of glucose if the child is in diabetic acidosis. The emotional response of the diabetic child to insulin shock usually tends to follow a stereotyped pattern characteristic of the individual. The variations in response are somewhat similar to those of different persons to alcoholic intoxication. Thus one child may become despondent and cry readily, whereas another one is exuberant and even hilarious, and an occasional child becomes belligerent.

Insulin shock is, under ordinary circumstances, such a transient affair, and the disappearance of symptoms is so complete, that there is often failure to recognize that it may have serious consequences. When insulin shock of an extreme degree is allowed to persist, there may be cerebral damage responsible for permanent motor defects, mental deficiency and even death.

**Supervision of the diabetic child.** Diabetic children can be normally healthy and active, and it is the physician's responsibility to assist the child and his family in making an adequate psychologic adjustment. Instruction in the daily care should be given to the patient and his family so that they can be essentially independent of the physician for the ordinary care of diabetes. These instructions should include (1) construction of a diabetic diet and especially variation of menus to avoid monotony; (2) administration of insulin and minor adjustments in dosage which are required by changes in activity and even minor infections; (3) examination of the urine for sugar; (4) the keeping of daily records; (5) the need for personal cleanliness; (6) recognition of early signs of shock and method of treatment; and (7) recognition of early signs of acidosis and of the need for immediate medical assistance. The diabetic child should assume his share of family responsibilities and compete on an equal basis with his schoolmates. He should not look upon his diabetes as a handicap or as a reason for asking for quarter.

Unfortunately a truly adequate psychologic adjustment by the child and his family is frequently not attained. In some instances this is largely due to the physician, owing to his failure to provide early guidance and particularly to his failure to permit the child and

his parents to achieve a sense of sufficiency for the ordinary management of the diabetes. The daily management can become as routine as other features of personal hygiene. No attempt should be made to hide the fact that the child has diabetes; on the other hand, it should not be used as a "crutch" or defense mechanism. The child should be permitted and encouraged to develop his natural talents, but the *sense of direction* should exist in him. The differences in the attitudes and adjustments of diabetic children in various clinics attest to the importance of guidance by medical and ancillary personnel—or in certain respects, perhaps, to lack of it.

During adolescence the problems of the diabetic child are likely to be accentuated. Rebellion at the regularity of insulin injections may result in lapses of medication and hence acidosis, or rebellion may be expressed in other ways, such as aggressiveness or withdrawal and even delinquency. Parents and doctors require a fine understanding, and above all they must have the confidence of the child if he is to be brought to maturity adequately adjusted to compete on an equal basis with his peers.

### THE DIABETES MELLITUS SYNDROME IN THE NEWBORN INFANT

A few instances of a transient state of diabetes mellitus developing in the newborn period, persisting for weeks or months and terminating apparently in complete recovery, have been reported. Clinically, the syndrome fulfills the diagnostic requirements, viz., hyperglycemia, glycosuria and clinical control with exogenous insulin. The only minor variant is the absence of marked ketonuria; in the infant reported by Arey there was none, and in the one observed in our clinic only small amounts of acetone on isolated occasions. This response, however, is in keeping with Heymann's observation that the production of ketones in very young infants is much less than in older infants and children. Infection has not seemed to be an important instigating factor. The management is that of diabetes mellitus, but extreme care must be taken to avoid hypoglycemia and to determine when administration of insulin is no longer required. By contrast with the true disease, complete recovery occurs and, so far as is known, is permanent.

True diabetes mellitus is also rare in newborn infants, but it does occur. Differentiation from the transient state can be made only

after sufficient time has elapsed to determine whether the diabetic state is permanent.

## INFANTS OF DIABETIC MOTHERS

The high fetal and neonatal mortality rate of infants of diabetic mothers has long been known, but to date no complete satisfactory explanation for it has been presented. Numerous theories have been proposed; one which has received widespread attention is that the neonatal mortality rate is due to hypoglycemia. Numerous workers have claimed, however, that the blood sugar levels of infants of diabetic mothers differ in no way from

those of infants of comparable gestational age born of nondiabetic women. Recently the problem was reopened by Reardon and her co-workers, who maintain that infants with clinical disturbances have sustained low values for blood glucose as compared to healthy infants of nondiabetic mothers delivered either by the vaginal route or by elective cesarean section. In addition to the hypoglycemia they find a respiratory and metabolic acidosis in many of the infants and hyperphosphatemia and hyperkalemia in some.

Infants of diabetic mothers may show a completely normal course or may exhibit a typical clinical disturbance. This consists in respiratory distress which may be marked immediately after delivery or may be minimal at birth and becomes severe in a few hours following delivery. The respiratory distress consists in rapid respirations with or without cyanosis, inspiratory retractions of the soft tissues of the chest and a constant irritable cry. These signs increase in severity during the first two or three days of life and end in respiratory failure or gradually decrease over the same period of time. Physical examination reveals poor aeration of the lungs and inconstant rales throughout the lung fields. A roentgenogram of the chest reveals a generalized fine granular atelectasis.

Other striking findings on physical examination are the large size of the infant, which is inconsistent with his gestational age, and edema which is generalized and nonpitting.

Miller suggests that the respiratory difficulties of these infants are due to cardiac enlargement and failure. The author, however, has not observed cardiac failure frequently and attributes the respiratory signs to pulmonary hyaline membranes, which are present more frequently in infants of diabetic mothers than in infants of normal mothers. It is possible, however, that cardiac failure may play a role in the production of pulmonary hyaline membranes.

Warren and LeCompte have reviewed the autopsy findings of a series of fifty infants of diabetic mothers and have re-emphasized the large size and visceromegaly of these infants. The most characteristic finding was hyperplasia of the islets of Langerhans and infiltration of the pancreas with eosinophilic leukocytes. Miller and others have pointed out that these findings are not only characteristic of the infants of mothers with clinical diabetes, but that they may also be found in infants born as long as fifteen years before

diabetes becomes clinically evident in their mothers. For these reasons it is wise to investigate for potential diabetes mellitus any woman giving birth to an unusually large baby.

Because the peak of fetal mortality of infants of diabetic mothers is reached after the thirty-sixth week of pregnancy, it is recommended that delivery of these infants be effected at or before this time. Since spontaneous delivery may be impossible, cesarean section is often required. Hormonal therapy to diabetic mothers during pregnancy has been stressed by White, but is still a highly controversial subject.

**Treatment.** It is recommended that a pediatrician attend the delivery of infants of diabetic mothers and be responsible for the immediate care of the infant. In view of the large amount of amniotic fluid in the stomachs of these infants, especially when delivered by cesarean section, the stomach should be emptied after clearing the upper airway.

The infant should be followed up closely after birth. A rising respiratory rate indicates early distress and may soon be accompanied by retractions. If oxygen is needed, a high humidity is recommended. It is now felt that antibiotics should not be given prophylactically, but administered only if infection occurs or is suspected. The author has delayed the initial feeding of infants with respiratory distress and has not treated hypoglycemia except in the presence of convulsions. Reardon et al., however, claim excellent results from the administration by stomach tube or intravenous infusion of 30 ml. per pound per day of 5 per cent glucose in 0.45 per cent sodium chloride solution. Further controlled studies are needed to evaluate these findings.

If signs of distress do not develop during the first twenty-four hours of life, they are unlikely to occur subsequently. Infants with respiratory distress have increasing difficulty, death occurring in forty-eight to ninety-six hours, or, over the same period of time, there is gradual improvement in aeration with disappearance of abnormal signs. The basic cause or causes of the high incidence of pulmonary hyaline membranes in these infants are not clear.

Although the incidence of lethal congenital abnormalities in infants of diabetic mothers is about three times higher than in infants of nondiabetic mothers, malforma-

tions account for only a small proportion of the deaths.

## HYPOGLYCEMIA

Hypoglycemia is an abnormally low level of blood glucose. The concentration of *true* blood glucose\* in normal infants and children after a twelve-hour fast ranges from 80 to 100 mg. per 100 ml. In normal infants during the first five days of life values as low as 20 to 60 mg. are not uncommon. The fasting blood glucose levels may be altered by various physiologic influences, which should be considered in the interpretation of such values. Loud crying or extreme fright may

\* Many reducing substances in addition to glucose are present in blood. Determination of the so-called total true blood glucose value by the Somogyi-Nelson method before and after yeast fermentation has demonstrated that galactose may constitute a considerable portion of the blood sugar value in many normal and sick infants.

elevate the blood sugar as a result of adrenal stimulation—the so-called alarm reaction. Hartman considers any true blood glucose value below 50 mg. as hypoglycemia, whereas Conn regards only values below 40 mg. per 100 ml. as significant. A low blood sugar value may be designated as clinically significant hypoglycemia only when associated with characteristic clinical manifestations which disappear as the blood sugar concentration rises.

**Physiologic Considerations.** The almost constant level of the fasting blood glucose level represents a dynamic balance between the rate of flow of glucose into the blood from the liver and the rate at which glucose is withdrawn from the blood by the tissues to be utilized or stored as glycogen.

The absorption of glucose from the intestinal tract is not a passive process. Glucose is drawn into the cells by the energy of conversion of the inert glucose molecule into the reactive phosphorylated form, glucose-6-phosphate. A constant flow of glucose into the body fluids from the intestinal tract is thus ensured, even when a high blood glucose concentration would act as an osmotic barrier to a more dilute glucose solution in the intestinal lumen. As glucose is discharged into the circulation by the cell, the coupled phosphate is removed. The impaired intestinal carbohydrate absorption associated with hypothyroid states, and the enhanced absorption seen in hyperthyroidism, stem from the regulatory influence which thyroid hormone has on this phosphorylating mechanism.

Absence of glucose from the urine under normal conditions results from a similar activity by renal tubular cells by which glucose is rapidly and completely withdrawn from the glomerular filtrate by phosphorylation. The glycosuria induced by administration of phlorizin is due to depression of the tubular mechanism which reabsorbs glucose.

As glucose enters a cell it is immediately phosphorylated to glucose-6-phosphate by the enzyme hexokinase, utilizing phosphate from adenosine triphosphate (ATP). Depending on the immediate needs of the cell, glucose-6-phosphate may follow one of several metabolic pathways. It may be burned to supply cellular energy in an orderly progression of breakdown which is conveniently divided into two parts: (1) the *Embden-Meyerhof cycle* of glycolysis, a series of phosphorylated compounds to the stage of three-carbon atom compounds (pyruvic and lactic acid); (2) the *Krebs tricarboxylic acid cycle* of reactions

in which phosphate is removed from pyruvic acid by the enzyme transphosphorylase. Following the metabolic pathway of the Krebs cycle of six organic acids, pyruvate is then burned to carbon dioxide and water. The part of the pyruvate which does not enter the Krebs cycle is utilized for the formation of body fat (lipogenesis) by synthesis into fatty acids.

Glucose-6-phosphate in excess of the cell's energy requirement may be stored as glycogen by preliminary change to glucose-1-phosphate, from which the phosphate is removed by the enzyme phosphorylase, and polymerization into inert glycogen occurs. In the reverse process of glycogenolysis, glycogen is broken down to glucose-6-phosphate, which in turn may be burned via the Embden-Meyerhof cycle or be regenerated into glucose by the enzyme glucose-6-phosphatase, which is present in liver, but not in muscle cells. The absence of this specific phosphatase from muscle explains why muscle glycogen does not furnish glucose to the body fluids. In all other aspects the pathways of glucose metabolism are believed to be similar in liver and muscle. The reactions and enzymes involved in the metabolic transformation of glucose are shown in Figure 63 (p. 269).

The hexoses fructose, galactose and mannose have no complete metabolic pathways of their own in the cell, but are utilized for energy or the formation of glycogen by introduction into the stream of glucose metabolism after phosphorylation by hexokinase.

Endocrine influence on glucose metabolism is exerted through direct action on specific enzymes. Hormonal stimulation of the hexokinase system by insulin increases the rate at which glucose is withdrawn from the blood by formation of glucose-6-phosphate in the cells; the effect is hypoglycemia. Hexokinase activity may be inhibited by anterior pituitary growth hormone, perhaps by adrenal glucocorticosteroids and by epinephrine. The action of these three hormones leads to hyperglycemia.

Increased activity of hepatic phosphorylase results in acceleration of glycogenolysis with elevation of the blood sugar by the regenerated glucose. Two hormones, epinephrine and glucagon (the pancreatic hyperglycemic factor), have an enhancing effect on phosphorylase action. Hypoglycemia may therefore have its origin in (1) excess of circulating insulin; (2) lack of anterior pituitary growth hormone, glucocorticosteroids or glucagon; (3) liver damage.

**Etiology.** It is readily apparent that hypoglycemia may result from a wide variety of etiologic factors. Since rational treatment and prognosis vary, depending upon the basic disorder, it is essential to make every reasonable effort to determine the etiology.

**Hypoglycemia due to defective intestinal absorption of glucose.** Unlike most adults, children and especially infants may exhibit lowering of the blood sugar level when carbohydrate is withheld for twenty-four to forty-eight hours. However, fasting by itself is rarely, if ever, a cause of clinical hypoglycemia, but may be a precipitating factor when other defects that may cause hypoglycemia are present. This is also the case when the blood sugar values are lowered by impaired intestinal absorption as is the case in chronic diarrhea, celiac disease, intestinal tuberculosis and the edematous phase of the nephrotic syndrome. Thyroxin influences the rate of intestinal absorption of hexoses by its regulatory effect on the phosphorylation process. The hypoglycemia seen at times in cretins is partially due to this absorptive defect.

**Hypoglycemia due to renal glycosuria.** Glycosuria due to defective tubular reabsorption of glucose occurs in a variety of clinical entities. It is encountered as an isolated hereditary condition, and is also part of the de Toni-Fanconi syndrome, presumably owing to hereditary absence of the tubular enzyme system which phosphorylates glucose. Glycosuria in some patients with lead poisoning and that following administration of phlorizin or dinitrophenol results from poisoning of the renal tubular system. In rare instances renal glycosuria has lowered the blood sugar to hypoglycemic levels.

**Hypoglycemia due to hyperinsulinism.** Hypoglycemia may result from an absolute or relative excess of insulin secretion.

**ORGANIC HYPERINSULINISM.** Secretion of excessive amounts of insulin which occurs in hyperplasia or adenoma of the beta cells of the islets of Langerhans is the organic type of true hyperinsulinism. There is an erroneous concept that hypoglycemia and organic hyperinsulinism are synonymous. This is unfortunate, since most instances of hypoglycemia in childhood are due to causes other than true hyperinsulinism.

The primary adenoma of the islet cells (nesidioblastoma), relatively common in adults, is an extreme rarity in children.

Hypoglycemia resulting from hyperplasia of the islets may occur in newborn infants of diabetic and prediabetic mothers. The fre-

quently encountered symptoms of cyanosis, dyspnea and tachypnea and the high mortality rate of such infants are not solely attributable to the low blood glucose levels (p. 1214). It is of interest that hyperplasia of the islets of Langerhans has been observed in infants dying of erythroblastosis fetalis.

**FUNCTIONAL HYPERINSULINISM.** Nervous impulses through the right vagus originating in the hypothalamic parasympathetic center can stimulate insulin secretion, and a functional type of true hyperinsulinism based on such abnormal nervous stimulation has been postulated.

Fundamentally, the prime factor in the adjustment of the blood sugar concentration is the blood sugar level itself. Thus hyperglycemia, acting as a stimulus to insulin secretion, will, in the presence of hyperreactiveness of this mechanism, result in a functional type of true hyperinsulinism. Such patients have hypoglycemic reactions two to four hours after a meal or a glucose tolerance test, but not after fasting. In organic hyperinsulinism hypoglycemic attacks occur both postprandially and after food deprivation as well as during hyperpyrexia or strenuous muscular exercise, when the increased oxidation of glucose by the tissues is a contributing factor.

Infants with galactosemia frequently have hypoglycemic reactions due to functional hyperinsulinism. Galactose is present in the body fluids of such infants because of a hepatic defect, which may be congenital and permanent or may occur as a temporary abnormality in newborn and young infants. Hypergalactosemia is as effective as hyperglucosemia in evoking an increased secretion of insulin which lowers the blood glucose to hypoglycemic levels, but leaves circulating galactose intact. Since ordinary clinical methods of blood sugar determinations do not differentiate glucose and galactose, this phenomenon accounts for the occurrence of hypoglycemic reactions in infants with seemingly normal levels of blood sugar.

**Hypoglycemia due to pituitary and adrenal cortical insufficiency.** Corticotropin and growth hormone are the principal anterior pituitary hormones with carbohydrate-regulating properties. The effect of corticotropin on carbohydrate metabolism is an indirect one through its control of adrenal secretion of glucocorticosteroids. The principal actions of the glucocorticosteroids on carbohydrate metabolism are to increase gluconeogenesis mainly from protein and to decrease tissue utilization of glucose. The latter may be due

in part to inhibition of hexokinase activity. A deficiency of corticotropin or adrenal cortical secretion results in depression of gluconeogenesis and increased tissue utilization of glucose and hence in hypoglycemia.

The hypoglycemia occasionally noted in congenital adrenal hyperplasia is due to inability of the adrenal cortex to produce adequate amounts of hydrocortisone.

Growth hormone appears to decrease peripheral utilization of glucose, but the mechanism is unknown. Deficiency of growth hormone is partially responsible for the hypoglycemia of hypopituitarism.

**Hypoglycemia due to decreased delivery of glucose into the blood by the liver.** Severe hepatic damage produced experimentally or by disease may involve all three of the hepatic mechanisms of carbohydrate metabolism: viz., impairment of (1) *glycogenesis* results in an inadequate storage of glycogen; of (2) *gluconeogenesis*, in the conversion of fatty acids and amino acids (derived from body fat and tissue protein) to glucose and glycogen; and of (3) *glycogenolysis*, in a decreased ability of the liver to deliver glucose to the blood.

Hypoglycemic manifestations may be produced by such hepatotoxic agents as phosphorus, carbon tetrachloride, chloroform, hydrazine, neoarsphenamine, salicylates and white snake root (milk sickness), and during acute and chronic infectious hepatitis, often as a terminal event.

Extensive infiltration of the liver by neoplastic cells, fibrous tissue, granulomas or fat may lead to hypoglycemia. It is obvious that in the aforementioned conditions hypoglycemic manifestations are secondary to the symptom of hepatic disease.

Hepatic glycogen disease (von Gierke's disease) (p. 268) is a cause of hypoglycemia due to defective glycogenolysis.

The rate of breakdown of hepatic glycogen to glucose is regulated by the enzyme phosphorylase. Both epinephrine and glucagon increase blood sugar levels by increasing the activity of the phosphorylase enzyme system. McQuarrie has described two children in one family in whom hypoglycemia was presumed to be due to a deficiency of glucagon, because no alpha cells could be demonstrated in biopsied pancreatic tissue. There are no known cases of hypoglycemia secondary to absence or failure of epinephrine activity.

**Idiopathic hypoglycemia of infancy.** In most instances of hypoglycemia in the pediatric age group no pathologic lesion can be

identified. The symptoms usually begin in early infancy, and there is a tendency to spontaneous improvement in subsequent years. In the absence of an understanding of the pathogenesis such cases of hypoglycemia have been termed *idiopathic hypoglycemia of infancy*. McQuarrie's observations of absence of the alpha cells of the pancreas in two siblings with hypoglycemia has not been noted in other patients. It has recently been demonstrated that in some instances of this disorder a fall in the fasting blood glucose level follows ingestion of a high protein feeding, a casein test meal or administration of leucine (p. 267).

This group is probably a heterogeneous one consisting of several different defects. Familial tendencies have been observed.

**Clinical Manifestations.** There are no exact relationships between the levels of blood sugar and the development or severity of symptoms. The rate of fall of the blood sugar seems to be a determining factor for the appearance of symptoms; a rapid fall, irrespective of the actual level reached, is most likely to bring on symptoms. The time of occurrence of symptoms in relation to muscular activity, fasting and food intake has differential diagnostic value. Hypoglycemic manifestations which appear only several hours after a meal are due to functional hyperinsulinism. Symptoms occurring in the morning or after vigorous activity are more indicative of organic hyperinsulinism. Even at extremely low blood levels of glucose children show great variability in symptoms. Many become conditioned to repeated hypoglycemic episodes or to hypoglycemia of long duration, so that they cease having symptoms. The symptoms of hypoglycemia are derived chiefly from disturbances of the central nervous system. Nerve tissue has little stored carbohydrate and, unlike other tissues, cannot utilize protein or fat, so that it is dependent upon a continuous supply of blood glucose in adequate amounts to maintain its normal functions.

Hypoglycemic symptoms are protean, but often produce more or less characteristic patterns in individual patients. Some of the more frequent symptoms are fatigue, headache, pallor, sweating, speech and visual disturbances and motor disturbances, such as tremulousness, incoordination, paralyses, syncope and convulsions. Hunger is prominent, and vomiting not infrequent. The temperature is often subnormal. Tachycardia and extrasystoles occur as a result of stimulation

of the sympathetic nervous system. Psychic disturbances such as irritability, negativism, drowsiness and alterations in behavior are seen in older children. In the ranks of emotionally disturbed children there are certainly some unhappy, ill-behaved or maladjusted children requiring, not guidance, but more sugar.

In newborn and young infants recognition and evaluation of symptoms may be difficult except as the possibility of hypoglycemia is considered. Convulsions are often the manifestation recognized initially.

Mental deterioration and demonstrable permanent cerebral damage may result from protracted or repeated hypoglycemic episodes.

**Diagnosis.** Two distinct diagnostic problems are posed: (1) the detection of hypoglycemia, and (2) the determination of the disturbed regulatory mechanism. There is unfortunately no routine and simple laboratory test for the screening of patients with hypoglycemia.

The most effective means for the establishment of the hypoglycemic state are the determination of fasting blood sugar levels and the glucose tolerance test. Patients whose symptoms occur in the fasting state would be expected to have a low blood sugar level before breakfast. If the fasting blood sugar level is normal after a simple overnight fast, then a more prolonged fast period, even as long as twenty-four hours, may be necessary to provoke symptoms and to demonstrate hypoglycemia. When symptoms tend to occur several hours after meals and not before breakfast, a six-hour glucose tolerance test is indicated. In many instances both tests should be performed.

When it is established that hypoglycemia is present, it is necessary to determine the etiology. If there is fasting hypoglycemia, the conditions to be considered in the differential diagnosis are severe renal glycosuria, hepatic disorders, anterior pituitary insufficiency and adrenal cortical insufficiency. If hypoglycemia is evoked by a carbohydrate load as with the glucose tolerance test, functional hyperinsulinism is the most likely explanation. If both fasting and postprandial hypoglycemia are demonstrated, organic hyperinsulinism and "idiopathic spontaneous hypoglycemia of infancy" must be considered.

The *epinephrine tolerance test* is a useful procedure to study the hepatic glycogenolytic mechanism. A flat curve indicates an abnormally rapid rate of glycogen depletion, a failure of glycogen formation by hepatic dis-

ease or hepatic glycogen (von Gierke's) disease.

Talbot recommends that the test be carried out in the following manner: To provide an adequate glycogen supply in the liver, a diet containing 6.5 gm. of carbohydrate per kilogram per day (180 gm. per square meter) is given daily for three days before the test. Omitting breakfast on the fourth day, 0.01 cc. of 1:1000 epinephrine per kilogram (0.3 cc. per square meter) is injected subcutaneously. Sugar determinations are done on blood samples taken at fifteen, thirty and forty-five minutes. A rise of blood sugar of at least 20 mg. per 100 ml. should occur during this time if hepatic glycogenolysis is normal.

The *intravenous glucose tolerance test* as described below evokes the secretion of insulin which brings the blood glucose content to normal levels in about two hours. As the glucose level continues to fall below normal under the influence of continued insulin secretion, the insulin antagonists (epinephrine, glucagon and glucocorticosteroid) cause the blood glucose level to rise and return to a normal value by the third hour. In the patient with hypoadrenocorticism or a deficiency of glucagon insulin continues to act unopposed, and the steadily falling blood glucose reaches hypoglycemic levels within four to six hours.

The patient is prepared for this test by the feeding of a diet containing 6.5 gm. of carbohydrate per kilogram (180 gm. per square meter) for three days. Before breakfast on the fourth day, after a twelve-hour fast, 0.7 gm. of glucose per kilogram (20 gm. per square meter) is administered intravenously as 10 or 20 per cent solution over a thirty-minute period. Blood samples are obtained before and at one-half, one, two, three, four and five hours after the injection.

Although deficiency of glucocorticosteroids as in Addison's disease or Simmonds' disease is frequently associated with hypoglycemic manifestations, hypoglycemia is rarely the presenting complaint. Other signs and symptoms of adrenal insufficiency are often present and lead to recognition of the disorder (pp. 1154, 1183).

The *insulin tolerance test* provides a more direct method of determining the response to hypoglycemia, but its use is not often necessary. Normally there is a prompt fall in the fasting blood sugar followed by a return to the fasting level in two hours. Failure of restoration of normoglycemia in two hours has the same significance as described for the intravenous glucose tolerance test. This test is not without danger in the hypoglycemic child and should never be done without con-

stant surveillance during the procedure and without provision to terminate the hypoglycemia promptly if alarming symptoms develop.

The *insulin tolerance* test is performed by administering 0.1 unit of regular insulin per kilogram after a three- or four-day period on a normal diet and immediately after a night's fast. Blood for sugar determinations is obtained before the injection of insulin and fifteen, thirty, forty-five, sixty, ninety and 120 minutes thereafter. In the normal child the blood sugar drops to about 50 per cent. of the fasting level in fifteen to thirty minutes and returns to normal in sixty to ninety minutes. The child should be observed closely for symptoms of hypoglycemia, which include irritability, faintness, headache, dizziness, sweating, tremor and visual disturbances. Mental confusion is a grave sign and is an indication for immediate termination of the test by the administration of glucose. When an unusual degree of insulin hypersensitivity is suspected, one-half or one-third of the dose of insulin should be used for the initial test.

Abnormal *electroencephalographic patterns* resulting from hypoglycemia are difficult, if not impossible, to differentiate from those occurring in epileptic patients. In patients with infrequent hypoglycemic attacks the abnormalities in the electroencephalogram are usually not present between attacks. It is likely that cerebral defects are the result rather than the cause of hypoglycemia.

**Treatment.** The immediate symptoms of hypoglycemia may be relieved by administration of epinephrine (0.03 ml. or  $\frac{1}{2}$  minim of 1:1000 solution per kilogram of body weight; not to exceed 0.8 ml.) and/or of glucose, orally or intravenously. In patients with hypoadrenocorticism more severe hypoglycemia may recur four to six hours after intravenous administration of glucose. Similarly, reliance should not be placed upon high carbohydrate meals to prevent recurrent attacks of hypoglycemia, for frequently the opposite effect is obtained. The severe postprandial fall in blood sugar is responsible for the symptoms of hypoglycemia. Between-meal lunches and one before bedtime are often effective. An increase in the protein content of the diet at the expense of carbohydrate is strongly advocated by Conn on the grounds that glucose is produced at a slow rate from protein and does not provide the hyperglycemic stimulus which elicits secondary hypoglycemia. However, in hypoglycemia of hepatic origin the diet should be high in both carbohydrate and protein.

An occasional patient with "idiopathic

spontaneous hypoglycemia" may have more severe hypoglycemia with diets high in protein (q.v.). It is probably desirable to test the glycemic response of all patients with idiopathic hypoglycemia after a test feeding of casein or leucine. Feeding small amounts of carbohydrate thirty to forty minutes after the normal feeding may prevent the fall of blood sugar in such patients.

Hydrocortisone restores normal carbohydrate metabolism in patients with corticotropin or adrenal cortical insufficiency. Corticotropin has been effective in maintaining normal glycemic levels in infants with idiopathic hypoglycemia (McQuarrie). Hydrocortisone and other glucocorticosteroids administered orally appear to be equally effective. The dose must be adjusted to the individual needs of the patient, but at the lowest effective level. Every six months or so attempts should be made to discontinue the drug gradually.

In the patient with protracted hypoglycemia, unresponsive to diet, corticotropin or corticosteroids, and in whom no pancreatic adenoma is demonstrable on surgical exploration, more radical measures have been used. Partial pancreatectomy has usually had little, if any, palliative effect. Two such infants have been treated with apparent success with alloxan (mesoxalyl urea).

Psychologic guidance of the hypoglycemic child and his family is of paramount importance.

## METABOLIC DISORDERS WITH OSSEOUS LESIONS

See also Parathyroid Disturbances (p. 1175), Cystinosis (p. 263) and Diseases of the Renal Tubules (p. 261).

### VITAMIN D-REFRACTORY (RESISTANT) RICKETS

Vitamin D-refractory rickets may now be the most common form of rickets in the United States. Vitamin D-deficiency rickets—once the scourge of childhood—has almost vanished in this country. In vitamin D-refractory rickets the usual prophylactic doses of vitamin D do not prevent the development of severe rickets, and if adequate therapy is not provided, there are severe bony deformities and dwarfism (Fig. 350). The roentgenographic changes in the long bones are similar to those of vitamin D deficiency rickets. The usual chemical changes in the blood are a high alkaline phosphatase and a hypophosphatemia. In exceptional cases the calcium level has been low, and the patients have had clinical tetany. These patients have responded to extremely large doses of vitamin D, as have those with hypophosphatemia and normal calcium levels. In both types healing of the rickets can usually be obtained even though deformities have occurred; the deformities are persistent, except as they can be partially corrected by orthopedic means.

There appears to be a hereditary factor, although the mode of inheritance has not been satisfactorily established. In a large North Carolina kindred hypophosphatemia was found to be inherited as a sex-linked dominant. Although several members had vitamin D-resistant rickets, there was no clear genetic mechanism to explain the presence of rachitic lesions in this kindred. The basic

metabolic defect is undetermined; an abnormally high renal clearance of phosphorus has been demonstrated. Absorption of vitamin D from the intestine is not impaired.

The basis of *treatment* is administration of large doses of vitamin D; the amount varies in different patients and even in the individual patient. The required dosage ranges from 5000 to 1,000,000 units a day and in general is higher during the infantile and adolescent growth spurts. A practical plan is to start with 50,000 units of vitamin D a day, subsequent adjustments being based principally on roentgenographic observations. Serum calcium and phosphorus concentrations and alkaline phosphatase activity are determined at monthly intervals until stabilized and then at intervals of two to four months. The serum inorganic phosphorus rarely returns to normal levels, but the rickets heals with adequate therapy. The parent or patient is instructed to test the urine two or three times weekly with Sulkowitch's reagent\* in order to detect any tendency to hypercalciuria. If there are several 4 + reactions, the patient should be re-evaluated by measurement of the serum calcium level. Hypercalcemia is an indication for reduction in the dose of vitamin D. Orthopedic correction of deformities should never be undertaken until the rachitic process is inactive. Close supervision is necessary when the child

\* Sulkowitch's reagent:

Oxalic acid, 2.5 gm.  
Ammonium oxalate, 2.5 gm.  
Glacial acetic acid, 5.0 cc.  
Distilled water, qs. ad 150 cc.

The test: To 5 cc. urine add 2 cc. of the reagent. Readings are graded 0 to 4 + on the basis of the presence and extent of a white precipitate.

is immobilized for an appreciable time to avoid hypercalcemia and hypercalciuria with their resultant complications; reduction of the dose of vitamin D is usually indicated during this time. Supplemental vitamin D may not be required after growth has stopped, but this is not invariably so, and observation of the patient must be continued into adulthood.

## RICKETS ASSOCIATED WITH AMINO-ACIDURIA

(FANCONI-DE TONI-DEBRÉ SYNDROME)

The features of the syndrome are rickets, growth retardation, hypophosphatemia, amino-aciduria, glycosuria, normoglycemia and hyperphosphaturia. There is polyuria with in-

FIG. 350. *a*, Vitamin D-refractory rickets in a mother and her son. The mother's father probably had the same disease. The roentgenograms and the laboratory data refer to the boy: Calcium, 9.6 mg. per 100 ml.; inorganic phosphorus, 2.5 mg. per 100 ml.; serum phosphatase, 34.7 Bodansky units. *b*, Roentgenogram of the femurs showing bowing, thickening and rarefaction. Lower row: *A*, fraying of distal ends of radius and ulna. The distance between epiphyses and diaphyses of the radius and ulna is greater than normal. *B*, Roentgenogram 1½ years later. In the meantime the patient had had 50,000 to 200,000 I.U. of vitamin D daily. Epiphysal clefts show progress in calcification, but the chemical findings in the blood are essentially unchanged. Calcium, 9.6 mg. per 100 ml.; inorganic phosphorus, 2.3 mg. per 100 ml.; phosphatase, 23.7 Bodansky units.

creased excretion of organic acids, and often albuminuria. As in vitamin D-refractory rickets, there is increased renal phosphate clearance. Since hypokalemia has been observed in this syndrome, the possibility of its presence should be investigated prior to therapy. When glomerular function is not impaired, fixed base may be given in the form of sodium citrate, or a mixture of sodium and potassium citrate as described under Rickets Associated with "Base-Losing Nephritis." Fanconi recommends the use of basic sodium phosphate to replace the excessive phosphate loss. Excessive therapy with vitamin D may result in serious anorexia. The prognosis is poor.

There are differences of opinion whether cystinosis (p. 263) is a variant of this syndrome or whether they are two distinct entities. Some would combine the two under the category of de Toni-Fanconi syndrome, with or without cystinosis. Others suggest that amino-acid diabetes (Fanconi syndrome) results from a tubular defect in reabsorption of certain amino acids, whereas cystinosis results from a defect in methionine metabolism.

#### **RICKETS ASSOCIATED WITH HYDROPHthalmos, ORGANIC ACIDURIA AND DECREASED RENAL AMMONIA PRODUCTION**

Lowe identified a syndrome consisting in congenital glaucoma, decreased renal production of ammonia, rickets, organic aciduria and mental retardation. The patients observed were hyperactive and had episodes of fever without obvious cause. The plasma carbon dioxide content and pH were slightly but definitely low. Paper chromatography revealed nine to ten amino acids in the urine; cystine was not among them. The condition was unaffected by large doses of vitamin D alone, but the administration of calcium lactate and sodium citrate resulted in improvement of the rickets.

#### **RICKETS OF CHRONIC RENAL GLOMERULAR AND TUBULAR INSUFFICIENCY**

The classic form of "renal rickets" is that which develops as a result of chronic glomerular and tubular insufficiency. There is elevation of serum nonprotein nitrogen and inorganic phosphate, lowering of serum calcium concentration and systemic acidosis.

*This syndrome is often associated with congenital obstructive lesions of the urinary tract or malformations of the kidneys, or is secondary to severe renal infections. Hyperparathyroidism is a secondary manifestation apparently as a result of phosphate retention (p. 1179). These children usually die of renal failure.*

#### **RICKETS ASSOCIATED WITH "BASE-LOSING NEPHRITIS"**

(RENAL TUBULAR ACIDOSIS, RENAL HYPERCHLOREMIC ACIDOSIS, LIGHTWOOD SYNDROME, ALBRIGHT SYNDROME)

This syndrome appears to be due to a defect of the renal tubules resulting in an inability to excrete an acid urine. One hypothesis is based on a deficiency in the formation of ammonia; another, on a deficiency in the reabsorption of bicarbonate at average plasma concentrations and a deficiency of carbonic anhydrase in the tubular cells. When the defect is severe, symptoms appear in infancy. The principal manifestations are anorexia, vomiting, constipation, failure to thrive, apathy and irritability. Hypotonia, polyuria and dehydration may be manifest. Death may result from dehydration and acidosis. Osseous lesions are usually not found in these infants. Appropriate treatment may result in permanent remission of the disorder.

In mild forms of the disorder the disturbance may be overlooked until the child presents with symptoms referable to the renal or osseous systems. There may be retardation of growth and bony deformities, or pathologic fractures may be the presenting complaint. Roentgenograms reveal changes similar to those of rickets and osteomalacia. These result from excessive loss of cations in the urine. Nephrocalcinosis and/or renal calculi also develop.

The unusual combination of an alkaline urine with a hyperchloremic acidosis is commonly present (Lightwood syndrome). Chemical changes in the serum consist in a low pH, low level of bicarbonate and a high level of chloride. In the patients with nephrocalcinosis the blood urea nitrogen may be elevated, and there may be inability to concentrate urine. Secondary hyperparathyroidism may develop and result in a lowered serum phosphorus level. In all instances the pH of the urine is high in relation to the metabolic acidosis and is often on the alkaline side.

*Therapy for base-losing nephritis consists*

in provision of supplemental sodium and potassium sufficient to more than compensate for the renal loss, supplementary dietary calcium and therapeutic doses of vitamin D to permit rapid remineralization of the skeleton. Although the additional dietary fixed base must be given continuously, the calcium and vitamin D therapy may be relaxed when adequate mineralization is demonstrable roentgenographically. Fixed base can be given in the form of a 30 per cent (w/v) solution of equal weights of sodium citrate and potassium citrate, 10 to 15 cc. per day in divided doses. The administration of sodium salts alone may result in chronic potassium depletion. An electrocardiogram or serum potassium determination should be obtained after the first twenty-four hours of therapy as a check on the possibility of potassium intoxication. The rachitic-like epiphyseal lesions show striking improvement with this therapy.

### RICKETS OF CELIAC DISEASE

(See also p. 721)

Patients with chronic steatorrhea may exhibit hypophosphatemia, hypocalcemia and rickets. Available evidence indicates that this condition is more likely the result of impaired absorption of vitamin D than of the formation of calcium soaps. Celiac rickets should be treated with large doses of vitamin D in a water-miscible vehicle by mouth. It is noteworthy that rickets is not a complication in patients with fibrosis of the pancreas; rickets may occur in association with biliary atresia.

### HYPOPHOSPHATASIA

(LOW PHOSPHATASE RICKETS)

Hypophosphatasia, first described as an entity by Rathbun in 1948, is characterized by abnormal mineralization of bone, diminished alkaline phosphatase activity and increased excretion of phosphorylethanolamine in the urine. The serum phosphorus level is normal, but the serum calcium level may be elevated in severely affected infants. It is an inborn error of metabolism which appears to be inherited as a simple recessive.

The clinical manifestations vary widely in severity. They may be present at birth, appear early in infancy or not become apparent until later. Systemic symptoms such as anorexia, irritability, vomiting, failure to thrive, seizures, recurrent episodes of cyanosis or pneumonia may be presenting complaints in infants. Older children are generally healthy,

and the initial manifestations may be orthopedic deformities such as genu valgum, growth failure or premature loss of deciduous teeth.

Roentgenograms of the bones reveal changes similar to those of rickets. There is disappearance of the zone of provisional calcification due to defective mineralization of osteoid tissue which may extend well into the diaphysis. In severely affected infants the skull is soft, and the fontanels and sutures appear large, owing to large areas of uncalcified osteoid. In older children the osseous lesions are less marked.

When the disorder starts early in infancy, it is usually severe, and a fatal outcome is the rule. Less severely affected patients may have a normal life expectancy, and gradual improvement of the osseous lesions may occur. Vitamin D, even in large doses, has no therapeutic value and may actually be harmful by producing severe hypercalcemia. Cortisone has been reported to benefit some patients, but further experience is necessary for its evaluation.

### IDIOPATHIC HYPERCALCEMIA WITH GROWTH RETARDATION

In 1952 Lightwood and Fanconi separately described a syndrome of idiopathic hypercalcemia in infants with failure to thrive. There appears to be a benign and a severe form. The onset is between two and nine months of age in either sex, with vomiting, anorexia, hypotonia and inadequate gain in weight. About half of the cases exhibited polyuria and polydipsia. Numerous cases have been reported in the British literature, but less than ten cases from North America. In some of the cases the facies has been described as "elf-like," with low-set ears, a thick upper lip and prominent epicanthal folds. The serum calcium concentration may be as high as 18 mg. per 100 ml.; the level of serum inorganic phosphorus is usually normal, except that it may rise with continuation of the severe form of the disease. The serum alkaline phosphatase activity is normal or low. The urinary excretion of calcium is normal or only slightly elevated. Roentgenograms of the bones may not reveal any abnormalities, or there may be some increased density at the ends of the long bones. Hypertension may be associated with increase of the serum inorganic phosphorus and blood urea nitrogen concentrations. Infants with the benign form of the disease may recover spontaneously

after a few months. Infants with the severe form tend to have osteosclerosis, albuminuria, persistent mental and physical retardation and renal failure. In the fatal cases renal calcinosis is common.

The *etiology* of this syndrome is unknown; an idiosyncrasy to vitamin D has been suggested by a number of writers. The great discrepancy between the number of cases reported from Great Britain and from North America has not been satisfactorily explained. The amount of vitamin D in the average infant's diet does appear to be somewhat lower in this country.

*Treatment* of the disease consists in provision of a diet without added vitamin D, and possibly restriction of calcium intake. Versene therapy is not recommended (one child died after intramuscular injection of ethylenediaminetetracetate). In the severe form the administration of 5 to 12.5 mg. of cortisone per day may be helpful.

# The Bones and Joints

A somewhat arbitrary arrangement of the various disturbances of the skeleton has been made on the basis of their etiology and of their management. In the first subsection are grouped the various anatomic defects. Many, but not all, of them are genetically determined, some develop in utero and others after birth. For the majority of these disturbances there is no therapy, but there are exceptions, as, for example, in the craniosynostoses, the

funnel chest deformities associated with cardiorespiratory embarrassment, or basilar impression (platybasia) associated with compression of the brain stem.

The section entitled Orthopedic Pediatrics includes the skeletal disturbances likely to be the joint concern of the pediatrician and the orthopedic surgeon. The remediable congenital dislocations and deformities are included in this division.

## SKELETAL DEFECTS

### DEFECTS IN OSSIFICATION OF THE SKULL

#### ANENCEPHALY

(ACRANIA)

See page 1075.

#### CRANIOSYNOSTOSIS

(STENOCEPHALY)

Premature closure of the sutures of the skull results in deformities of the head and often in damage to the brain and the eyes.

**Etiology.** The frequent association of premature synostoses of the skull with other skeletal defects suggests that the skeleton is adversely affected early in embryonic life.

**Pathology.** In the normal newborn infant the bones of the cranium are still somewhat separated, but soon after birth the definitive sutures are established. In the sutures the edges of the flat bones are separated by a layer of fibrous tissue which represents a remnant of the original membranous skull. Growth of the bones of the vault takes place in this fibrous strip; when the sutures are obliterated, this tissue ceases to grow and disappears. The definitive sutures, such as the coronal, sagittal and lambdoid, do not begin to close before the thirtieth year.

In the various forms of craniosynostosis one or several of these sutures are obliterated

before or soon after birth, and growth of the adjacent bones is inhibited in a direction at a right angle to the obliterated suture. As a result the diameter of the skull is reduced in this direction, and a compensatory growth takes place in regions where open sutures permit it.

FIG. 351. Craniosynostosis in a child 5 years of age who also had mental deficiency and paralysis of the ocular muscles.

FIG. 352. Acrocephalosyndactyly in a boy 12 years of age who also had obesity, hypogenitalism and mental deficiency. (See Laurence-Moon-Biedl syndrome, p. 1232).

**Clinical Forms.** In *scaphocephaly* the sagittal suture is closed prematurely, and a long and narrow head develops. The line of the obliterated suture is usually indicated by a prominent bony ridge. Pressure symptoms develop in many but not in all cases. Although there may be some elevation of intracranial pressure early, symptoms are usually not observed until functional closure of the other sutures occurs by about two years of age. Scaphocephaly affects males more often than females. Associated malformations are observed, and mental retardation occurs in some cases. Ocular complications are not frequent. Craniosynostosis may be found in patients with vitamin D-resistant rickets and affects more than one generation.

In *oxycephaly* there is a premature closure of the coronal suture, with occasionally premature closure of other sutures as well. In some instances the coronal suture is closed in its entire length; in others, in the lateral portions only, so that various types of deformities may develop. One speaks of a towerhead (*turriccephaly*) if the frontal, parietal and occipital bones ascend steeply and the vertex is dome-shaped. In other cases the head is pointed in the region of the anterior fontanel (*acrocephalus*) (Fig. 352). In asymmetry

of a stenocephalic head the term *plagiocephaly* is sometimes used. Premature closure of the coronal suture frequently leads to serious complications, since the brain or adjacent structures may be damaged by compression. The patient complains of headaches; frequently there is loss of vision, and at times there are convulsions. The roofs of the orbits are depressed, and exophthalmos develops. There may be strabismus and nystagmus, and examination of the fundi reveals papilledema or optic atrophy. The base of the skull and the facial bones are often hypoplastic. The palate is highly arched and sometimes cleft. Mental retardation is common. Other malformations such as cardiac anomalies, choanal atresia or defects of the elbow and knee joints and of the parietal bones may also be present. Syndactylism is the most frequently associated anomaly (see below). A familial form of oxycephaly associated with hemolytic jaundice has been reported.

*Acrocephalosyndactyly* is a syndrome consisting of acrocephaly and syndactyly of the hands (Figs. 352, 354) and sometimes also of the feet. A number of cases with syndactyly of the hands and polydactyly of the feet have been reported. As a rule, acrocephalosyndactyly occurs sporadically. Affected persons seldom have children, but an instance of the

FIG. 353. Craniosynostosis. The sagittal suture is narrow and bridged by bone (arrow). The skull was elongated in its anteroposterior dimension.

FIG. 354. Roentgenograms showing (A) acrocephalus and (B) syndactyly of the hand.

syndrome in a mother and a child has been observed.

*Craniofacial dysostosis (Crouzon's disease)* is a syndrome characterized by acrocephaly, a beak-shaped nose, hypoplastic maxilla, short upper and protruding lower lips, exophthalmos and external strabismus.

**Differential Diagnosis.** Oxycephaly must be distinguished from a familial form of high skulls in which premature closure of the sutures does not take place. Excessive growth of the adenoids is sometimes associated with a high skull and exophthalmos, but the sutures remain open. In microcephaly the head is small, owing to failure of the brain to grow; there are no evidences of increased intracranial pressure.

In craniosynostosis when there is compression of the brain, roentgenograms reveal convolutional atrophy, absence of one or more sutures, shallow orbits and underdevelopment of the sinuses, in addition to the abnormal shape of the skull. In acrocephalosyndactyly the phalanges are defective and fused with each other or with the metacarpal bones (Fig. 354).

**Prognosis.** During the first few years of life, when rapid growth of the brain may cause a spatial disproportion, the prognosis without treatment is doubtful. If no symptoms of increased intracranial pressure become noticeable in the first decade of life, the prog-

nosis is fairly good, and the chances for loss of vision are not great. In rare instances premature synostosis of the cranial sutures occurs as a hereditary trait which results in deformity of the skull without symptoms of spatial disproportion.

**Treatment.** If surgical repair is performed before there is significant cerebral or visual damage from compression of the brain, it appears that mental and visual defects can often be avoided. Furthermore, elimination of the cosmetic defect may have a significantly favorable psychologic effect. For these reasons operation is now recommended in some clinics as soon as the diagnosis is made in the first year of life.

If there are coronal or multiple synostoses, operation should not be delayed. The decision is more difficult in cases of isolated sagittal synostosis, since some children with this anomaly remain symptom-free. Surgical treatment consists in linear craniectomy along the prematurely closed suture and insertion of polyethylene film over the edges of the bone to prohibit its regeneration.

## PLATYBASIA

(OCCIPITALIZATION OR ASSIMILATION OF THE ATLAS, BASILAR IMPRESSION)

This condition may be primary or secondary. In *primary* platybasia, which is perhaps better

designated as occipitalization or assimilation of the atlas, there is a congenital malformation, with encroachment upon the upper cervical vertebral canal and posterior cranial fossa. For an understanding of this anomaly it is necessary to recall the fact that, embryologically, the occipital condyles and foramen magnum are derived from anlagen which resemble those of the first and second cervical vertebrae, which normally fuse with each other, but not with the upper cervical centers. In primary platybasia the first and second occipital segments and the first and second cervical vertebrae may all be fused into one bony mass, similar to the fusion or failure of segmentation of the cervical vertebrae below the second cervical vertebra in the Klippel-Feil syndrome.

*Secondary platybasia*, or basilar impression, occurs when disease has softened the cranial bones to such an extent that they no longer suffice to support the weight of the head. This may occur in rickets and certain forms of osteomalacia. The posterior cranial fossa is encroached upon as the cranial vertex approaches the occiput.

The importance of both primary and secondary platybasia is due to the effects upon the central nervous system. The medulla may be sharply kinked over the odontoid process of the second cervical vertebra, with resultant pressure upon the various spinal tracts. Localized thickening of the dura at the cranio-vertebral junction is frequently associated with these bony anomalies and contributes to the brain stem constriction. At times the loss of volume of the posterior fossa, through ap-

proach of the tentorium to the occiput, may produce foraminal hernia. A striking feature of platybasia is its tendency to remain asymptomatic in early life, neurologic changes becoming manifest from the fourteenth to the fortieth year.

The encroachment of the osseous structures upon the brain stem may be relieved in some instances by surgical means.

**Hypertelorism.** This condition, characterized by an abnormally large distance between the eyes and a broadening of the root of the nose, is a symptom and not a disease entity. It is often associated with mental deficiency and may be combined with other congenital defects. Mild forms may occur in otherwise normal children. The lesser wings of the sphenoid bone are overdeveloped, while the greater wings are relatively small. Hypertelorism can be transmitted through several generations.

### PARIETAL FORAMINA

These are irregularly shaped congenital defects with well defined margins symmetrically placed on each side of the posterior third of the sagittal suture. They are palpable, but frequently their presence is discovered roentgenographically. They may be inherited or occur sporadically and may be found in otherwise normal persons. At times they are associated with other congenital defects of the skeleton, eye, central nervous system and heart. They must be distinguished from defects of the skull associated with meningo-encephalocele or from defects caused by

FIG. 355. Hypertelorism in a girl 17 months of age (right) who also had a cleft palate and cleft lip. There was no bony deficiency of the forehead. The mother also had hypertelorism, and the father had a harelip. The picture shows contrast with normal child of about the same age.

FIG. 356. A typical example of lacunar skull (age, 18 days). Note the arborizing patterns of bony ridges which sharply delineate and separate rounded defects from one another. This patient had a large lumbosacral meningocele. (Vogt and Wyatt: Radiology, Vol. 36.)

syphilis, xanthomatosis, multiple myeloma or malignant metastases. Parietal foramina do not cause discomfort, and no treatment is indicated.

### LACUNAR SKULL

(LÜCKENSCHÄDEL)

This cranial anomaly is characterized by defects in the vault in the form of shallow depressions or deep cavitations extending to the outer surface and occurring mainly in the frontal or parietal areas. The thinned areas of bone are lined by dura and bordered by ridges of osseous tissue. The outer surface of the skull is smooth, but the inner table is rough, and in the irregular surface are many interlacing columns of bone surrounding oval depressions covered with a parchment-like membrane or a thin layer of bone. The roent-

genographic appearance is diagnostic and shows diminution in the thickness of the skull bones and variations in their density as irregular patches of rarefaction, or lacunas, with interlacing ridges of increased density (Fig. 356). Differentiation must be made from the generalized "hammered silver" or "digital impression" appearance of the skull bones which is observed on occasion without any apparent explanation for it and in other instances in association with increased intracranial pressure.

Meningocele is the most frequently associated defect. Lacunar skull can be detected in roentgenograms of about half of the infants with meningocele, particularly in those who have myelomeningocele or thoracic meningocele. When a meningocele is associated with a lacunar skull, progressive hydrocephalus is a frequent complication.

## DEFORMITIES OF THE EXTREMITIES

Severe defects of the extremities are only rarely compatible with viability. Children with so-called congenital amputations who survive infancy can be greatly benefited by prostheses and physical and psychologic rehabilitation. Minor defects are often encoun-

tered and require treatment as well as interpretation.

### MISCELLANEOUS DISTURBANCES

Complete absence of all extremities (*amelia*) or of one entire extremity (*ectromelia*) is a

FIG. 357. Hemimelia in an infant 11 months of age; picture taken at autopsy.

rare malformation. The term *hemimelia* is used for a defect of the distal parts of the extremities in which a tapering stump is formed. In *phocomelia* the proximal part of the extremity is defective, and a hand or foot seems to spring directly from the trunk (Figs. 357, 358). Individual bones may be absent. Absence of the humerus and ulna is rare; absence of the radius is usually associated with clubhand. Absence of the fibula is more frequently encountered than absence of the femur or tibia. As a rule, it is combined with pes valgus. Absence of the patella is indicated by a transverse fold of the skin in front of the knee joint during extension.

*Polydactyly* (supernumerary fingers or toes) may be found in a single member of

FIG. 358. Phocomelia and ectrodactyly in a girl 3½ years of age.

a sibship, but there are pedigrees in which polydactyly is inherited as a dominant trait. Polydactyly is sometimes associated with other malformations (see Chondro-ectodermal Dysplasia, p. 1237).

*Syndactyly* (Fig. 359), union of fingers or toes, may consist in fusion of the bones or webbing of the skin (*zygodactyly*). Syndactyly most frequently involves the third and fourth fingers and the second and third toes. It is often seen in children with multiple malformations (*acrocephalosyndactyly*) and in children who otherwise are entirely normal. In the latter, syndactyly is often hereditary.

*Split hand and split foot (lobster claw)* are deep clefts in the anterior part of the hand or foot, and the fingers and toes have different degrees of syndactyly. The foot appears split in the area where the second or third toe should be. The parts of the foot which lie on either side of the cleft are fused

FIG. 359. Syndactyly.

FIG. 360. Split feet (lobster claws) in a child whose mother, maternal aunt and maternal grandfather had similar malformations.

into masses in which terminal digits can be recognized (Fig. 360). Many pedigrees are known in which this malformation is inherited as a dominant trait. *Brachydactyly*, abnormal shortness of the fingers and toes resulting from lack of one of the phalanges, may be inherited as a dominant trait. *Clino-dactyly*, incurving of the little finger, may be inherited as a dominant trait. It is also often seen in mongolism. *Macroductyly* is a hypertrophy of one or several fingers and toes (Fig. 361).

A variety of skeletal defects, of which absence of thumbs and radii is common, occur at times in association with a congenital hypoplastic anemia (p. 935).

#### LAURENCE-MOON-BIEDL SYNDROME

This is a syndrome of retinitis pigmentosa, polydactyly, mental retardation, obesity and hypogenitalism, often with several members affected in a sibship. There is evidence that it is inherited as a recessive trait. The syndrome is not always limited to the five malformations mentioned, and incomplete forms of it are not rare. Dwarfism, acroceph-

FIG. 361. Macroductyly.

aly, oxycephaly, syndactyly, deafness and microphthalmos may also be associated with the syndrome (Fig. 352; see also p. 1162).

### DEFORMITIES OF THE VERTEBRAE, CLAVICLES, SCAPULAS AND STERNUM

#### CLEIDAL AND CLEIDOCRANIAL DYSOSTOSIS

This congenital syndrome is characterized by absence of the clavicles and often by delay of ossification of the skull. The defect is due to a developmental disturbance which is often genetic in origin and transmitted as a dominant trait. Other cases are sporadic and inheritance cannot be proved. Males and females are equally affected. The defective bones are usually membranous in origin. However, the ends of the clavicles, which are often also missing, are derived from cartilage, and other bones of cartilaginous origin are also affected.

**Clinical Manifestations.** The entire clavicle may be absent, or the sternal and acromial ends are present, but the connecting shaft missing. Sometimes the two ends are fairly well developed and joined by a narrow fibrous strip, thus simulating the appearance of a fractured clavicle on the roentgenogram.

In serious clavicular defect the shoulders can be approximated in front to a remarkable

degree (Fig. 362). The muscles which are normally attached to the clavicle may also be defective. At birth ossification of the calvarial bones is so delayed that the fontanels are excessively large and the sutures widely open. Large bosses develop on the frontal, parietal and occipital regions, and the skull assumes a globular shape, at times with a "hot cross bun" type of deformity, owing to depressions along the coronal and sagittal sutures. As the patient grows older, ossification of the calvarial bones progresses slowly, but the fontanels may remain open until adulthood. The sutures frequently close with interposition of wormian bones. The facial bones are underdeveloped, and the sinuses may be absent. The palate is usually highly arched and, in some cases, cleft. The dentition is irregular. Congenital cranial dysostosis may occur without anomalies of the clavicle. Deformities of the vertebrae and of the bones of the fingers and toes and delayed ossification of the pubic bones have also been observed. In hereditary cases the cleidal and the cleidocranial forms have occurred in the same sib-

FIG. 362. Cleidocranial dysostosis in a girl 5 years of age. (Cook: Arch. Pediat., Vol. 51.)

ship. The patients are usually of short stature, but their mentality and general health are unaffected.

**Diagnosis.** Roentgenograms of the chest reveal absence of the clavicles or nonunion of their ends; those of the head show a lack of ossification of the affected bones. The delayed ossification of the calvarium may suggest hydrocephalus, rickets or cretinism.

**Prognosis and Treatment.** The defects rarely cause discomfort or disability. Occasionally a clavicular fragment may press on nerves and cause pain; removal of the disturbing fragment is indicated.

### KLIPPEL-FEIL SYNDROME

In this syndrome there is a reduced number of cervical vertebrae, or there are multiple hemivertebrae formations fused into one osseous mass. Platybasia, spina bifida, scoliosis, torticollis, Sprengel's deformity or other malformations may be associated. External symptoms are shortness of the neck and lowering of the hairline. The motion of the neck is limited. In severe cases neurologic complications may develop.

### PTERYGIUM COLLI

(CONGENITAL WEBBED NECK)

In pterygium colli the skin of the lateral aspects of the neck forms a thick fold extending from the mastoid region to the acromial

process. Large folds of skin are also occasionally seen in the posterior parts of the neck. These anomalies are often combined with congenital lymphangiectatic edema of the hands and feet, high palate, cubitus valgus, deformities of the nails and ears and ovarian agenesis (see Turner's syndrome, p. 1198).

### SPRENGEL'S DEFORMITY

In this condition (Fig. 363) one or both scapulas are in a congenitally high position with the lower angle turned toward the spine. Sometimes a bridge of bone unites the spine to the scapula (omovertebral bone). The arm

FIG. 363. Sprengel's deformity, showing inability to raise the arm completely on the affected side.

on the affected side cannot be raised above a right angle with the body, and the head is inclined toward this side. Scoliosis is present. Sprengel's deformity may occur with the Klippel-Feil syndrome.

### WINGED SCAPULAS

This condition may result from underdevelopment or paralysis of the muscles which are inserted on the vertebral border of the scapula. It is sometimes a manifestation of a *scaphoid scapula*, which is characterized by a concave vertebral border.

### DEFORMITIES OF THE STERNUM

The two halves of the sternum may remain separated (*fissure of the sternum*). Pigeon

*breast* consists in a prominence of the sternum and the cartilaginous parts of the ribs, with lateral depressions of the thorax.

### PECTUS EXCAVATUM

(FUNNEL CHEST)

Funnel chest, or indentation of the lower part of the sternum, may be rachitic in origin or the result of chronic obstruction to respiration. In most instances, however, the condition is congenital. The reason for the defect is not apparent in all instances, but in some it is due to a short central tendon of the

diaphragm. The manubrium sterni is at the normal level, but the inferior parts are depressed, and the xiphoid may approach the vertebral bodies. The volume of the lung is decreased, and the heart displaced to the left. Respiration is paradoxical, since contraction of the diaphragm exerts a pull on the xiphoid and the costal cartilages. The patients appear round-shouldered, hollow-chested, thin and underdeveloped. The deformity may have untoward psychologic effects on the child.

There are differences of opinion as to the best age for repair and also as to the type of surgical procedure.

## DISTURBANCES IN OSTEOGENESIS AND IN ENDOCHONDRAL OSSIFICATION

### CHONDRODYSTROPHY

(ACHONDROPLASIA)

Chondrodystrophy is caused by a disorder of the cartilage which begins in prenatal life and leads to a specific type of dwarfism. Since the long bones of the extremities are affected to a greater extent than the vertebrae and the bones of the head, a disproportion of the extremities and the rest of the body becomes manifest (*micromelia*).

Since the skeletal changes depend upon a disturbance of endochondral ossification, the term *chondrodystrophy* appears appropriate. The term *achondroplasia*, indicating an absence of cartilage formation, is widely used, but does not correspond to the histologic picture.

**Etiology.** Genetic factors play a role in many cases, most pedigrees suggesting a dominant, some a recessive, mode of transmission. Sporadic cases occur. Bleyer considers advanced maternal age a possible etiologic factor. Males and females are equally affected.

**Pathology.** The basic process is a disturbance of endochondral ossification caused by an inability of the epiphysal plate to produce a sufficient amount of columnar cartilage. The result is deficient longitudinal growth of the bone. The rows of columnar cartilage also lack parallel arrangement and are of unequal length. The intercellular matrix of the cartilage has a fibrillar rather than a hyaline structure. The line of preparatory ossification is irregular. The bone trabeculae are short and thick and lack normal orderly arrangement. Sometimes a transverse vascular strip of connective tissue, which originates in the peri-

osteum, grows between the epiphysis and the diaphysis, thus adding another obstacle to longitudinal growth. If this strip affects only one side of the bone, the other side, which grows more rapidly, curves around the stunted half, and the bone becomes bowed. Periosteal ossification is little affected, so that transverse growth of bones is not greatly disturbed.

Short and thick bones are the result of such disproportionate growth. The epiphysal cartilage, which is underdeveloped in the longitudinal direction, may extend well beyond the shaft in the transverse direction, creating a mushroom-like enlargement. This hyperplastic type is more common in young children. In older persons hypoplasia of the cartilage is seen in the transverse as well as in the longitudinal direction, and the enlargement of the metaphysis is less pronounced (hypoplastic type). Owing to insufficient cartilaginous growth, the base of the skull is short, but the bones of the cranial vault which are of membranous origin continue to grow. This disproportionate growth results in a typical profile characterized by a broad nose with a depressed bridge, and a bulging forehead.

**Clinical Manifestations.** The chief characteristic of chondrodystrophy is the combination of short extremities with a head and trunk approximating normal size. The limbs are often curved and their epiphysal junctions enlarged and prominent. The shortness in the thighs and upper arms is greater than in the lower legs and forearms, and the hands, which are short and broad, may not reach below the hips. The plump fingers are not entirely parallel (Fig. 364). The relatively

large head exhibits a prominent forehead, flattening of the bridge of the nose, and a forward projection of the mandible; a slight degree of hydrocephalus is sometimes present. The chest is of normal length, but beading of the ribs and flaring of the costal margins are generally noticeable. The vertebral bodies are usually of normal height, but occasionally a wedge-shaped vertebra may be seen in the roentgenogram.

The thoracic kyphosis and the lumbar lordosis are usually accentuated. Protrusion of the abdomen and the gluteal region results in a characteristic posture (Fig. 364). An umbilical hernia is common. The chondrodystrophic pelvis has a kidney-shaped entrance, the promontory protruding forward. This deformity is an obstacle to delivery in females, often necessitating cesarean section. The gait is waddling, and subluxation of the deformed head of the femur sometimes occurs. Extension of the joints may be impeded by the irregular shape of the epiphyses. The skin is loose and may form transverse folds and pads. The muscular development is good. The mentality is usually normal, and chondrodystrophic dwarfs are reputed to be witty and entertaining.

Associated malformations such as harelip, cleft palate and polydactyly occur occasionally. In general, the endocrine glands function normally, although precocious puberty has been observed in several cases.

**Diagnosis.** The thickness of the bones and their irregular epiphysial ends as visualized in the roentgenogram make the diagnosis possible even in the newborn. The bones of the extremities are short and broad and show a mushroom-like broadening of the ends of the shafts. The fibula appears longer than the tibia. Curving may be seen in various places. At the epiphysial ends of the shafts are such irregularities as cupping, fraying and spurs. The mineral content is good throughout the bones, and there are no periosteal changes. Ossification of the epiphyses and of the carpal and tarsal bones is not delayed, but their outlines are irregular. The metacarpal, metatarsal and phalangeal bones are also short and thick and show irregularities of their epiphysial ends (Fig. 365). On the lateral view the base of the skull appears short. The bones of the vault bulge on all sides beyond the base.

The depressed bridge of the nose may suggest syphilis or cretinism. *Syphilis* can be ruled out by the roentgenogram and by serologic tests; normality in mental development

and of serum protein-bound iodine renders the diagnosis of *cretinism* impossible. A superficial examination of the roentgenograms may suggest *rickets*; however, the intensive calcification of the irregular epiphyses is characteristic of chondrodystrophy (Fig. 365).

Other forms of micromelia can be distinguished from chondrodystrophy by clinical examination or the roentgenogram. The legs of children with *osteogenesis imperfecta* or *osteopsathyrosis* may become shortened and deformed after repeated fractures, but the bones are long and slender. *Hypophosphatasia* resulting in congenital micromelia can be mistaken for chondrodystrophy in the neonatal period, but the deficiency of ossification and low serum phosphatase establish the diagnosis.

**Prognosis and Treatment.** Many children with chondrodystrophy die in utero or soon after birth, particularly when born prema-

FIG. 364. Chondrodystrophy.

FIG. 365. Chondrodystrophy of upper and lower extremities.

FIG. 366. Chondrodystrophia calcificans congenita. A, There is diffuse calcification of the laryngeal, tracheal and bronchial cartilages. In early infancy the infant had significant dyspnea, presumably due to the constricted tracheobronchial tree. B, Shortening of humerus. Numerous calcifications in the area of the elbow joint. Contractures of finger joints.

turely. Those who survive usually have good general health, and their mental development is satisfactory. Their height rarely exceeds 140 cm. (55 inches).

No specific treatment is known. Early orthopedic correction of developing deformities may improve the appearance.

### ATYPICAL CHONDRODYSSTROPHIES

#### CHONDRO-ECTODERMAL DYSPLASIA

(ELLIS-VAN CREVELD SYNDROME)

The combination of chondrodysplasia, ectodermal dysplasia, polydactyly and congenital heart disease is a rare syndrome. The bones of the extremities are short and thick, and the terminal phalanges of the fingers and toes and the nails are dystrophic. There is a sixth finger on the ulnar side of each hand. Dentition is defective, but the sweat glands and the skin are normal. The syndrome is probably inherited as a recessive trait.

#### CHONDRODYSSTROPHIA CALCIFICANS CONGENITA

This rare form of chondrodystrophy has a typical roentgenographic appearance. The carpal and the tarsal bones are replaced by numerous small but distinctly calcified spots scattered about the affected areas. They represent deposits of calcium in malacic cartilage. The epiphyses may be stippled with similar small calcium deposits. The limbs are short, particularly in their proximal segments (Fig. 366). Contractures are not rare, and cataracts are often present. Calcifications may also occur in the tracheal cartilages (Fig. 366) and be responsible for respiratory embarrassment.

#### MORQUIO'S DISEASE

(FAMILIAL OSSEOUS DYSTROPHY, HEREDITARY OSTEOCHONDRODYSSTROPHY)

The dwarfism produced by this condition clinically resembles that of rickets. The deformities of the spine, chest and extremities are similar to the end results of severe and untreated rickets. This type of chondrodystrophy is genetically determined. Consanguinity of the parents and also of the paternal grandparents was reported in the family described by Morquio. A recessive mode of transmission is suggested; in one unusual sibship the disorder was transmitted as a sex-linked recessive trait. Sporadic cases have also been described.

**Clinical Manifestations.** Development appears to be normal until the infant begins to

walk. The face and the skull are only slightly affected; the neck is short (Fig. 367). In contrast to typical chondrodystrophy, the spine and the chest become severely deformed in Morquio's disease. Fusion of cervical vertebrae and platybasia may occur. The thorax is short and broad; the anteroposterior diameter is increased, and the sternum protrudes. There is an exaggerated thoracic kyphosis of the spine and scoliosis of a varying degree. The abdomen protrudes; genital development is normal. The long upper extremities extend to the knees. The hands and fingers are long and soft. Genu valgum and flat feet are present. The joints are enlarged; the muscles and ligaments are flaccid; the gait is waddling. There are no characteristic chemical or serologic changes in the blood. Mental development is not impaired.

**Diagnosis.** There is an external resemblance to *rickets*, but the absence of hypophosphatemia and the roentgenographic appearance of the bones exclude rickets. In Morquio's disease, basilar invagination and occipitalization (platybasia) may be present in addition to anomalous segmentation of the cervical vertebrae. The vertebrae are flattened, and their cranial and caudal surfaces are uneven. The shafts of the long bones are of

FIG. 367. Morquio's disease.

FIG. 368. A, Gargoylism in a child 2 years of age, showing heavy features, depressed nasal bridge, kyphosis and stunting of growth; also outline of the enlarged liver. Child had corneal opacity and was mentally deficient. B, Typical spadelike hand in gargoylism.

normal length and shape. The outlines of their epiphysial ends are irregular, with flattening in some places and abnormal projections in others. The epiphyses are of irregular shape and sometimes fragmented. The ends of the metacarpal bones resemble those seen in typical chondrodystrophy.

In typical *chondrodystrophy* the head and trunk are large and the extremities short, whereas in Morquio's disease the head is of normal size, the trunk is short, and the extremities relatively long. In *gargoylism* the mentality is impaired, and a cloudy cornea and enlargement of the spleen and liver are found. There are, however, many atypical chondrodystrophies which cannot be distinguished with certainty from Morquio's disease.

**Prognosis and Treatment.** As far as physical development is concerned, the prognosis is unfavorable, since the deformities progress and become more pronounced. There is no specific treatment. Orthopedic treatment may prevent or correct the deformities to a certain extent.

#### GARGOYLISM

(HURLER'S SYNDROME, DYSOSTOSIS MULTIPLEX, LIPOCHONDRODYSTROPHY)

This disorder is the result of a metabolic disturbance which affects the skeleton as well as

soft tissues. Although the metabolic disturbance is present at birth, most of the symptoms develop in postnatal life. The fully developed disease exhibits cloudy corneas, hepatosplenomegaly, mental deficiency, skeletal changes and dwarfism. Both sexes may be affected. The disorder is genetically determined, most cases being due to a single recessive gene. Sex-linked recessive transmission has also been observed. The basic metabolic disturbance results in accumulation of an abnormal intracellular material which affects the cells and structure of many organs. The nature of the stored substances has not been determined, but they are thought to be mucopolysaccharides.

**Clinical Manifestations.** The skull is frequently malformed and may be scaphocephalic, oxycephalic or hydrocephalic. The closure of the anterior fontanel may be delayed. The supraorbital ridges are prominent, and the bridge of the nose is depressed. A profuse nasal discharge is usually present. The tongue is enlarged and the neck short. There is a kyphosis in the dorsolumbar region (Fig. 368, A). The heart is frequently enlarged, and a systolic murmur can be heard (p. 896). Dyspnea occurs on slight exertion, and cyanosis in advanced stages. The abdomen is prominent; the spleen and liver are

FIG. 369. Gargoylism. A, Lateral view of spinal column; B, hand.

enlarged; an umbilical hernia is frequently present. Externally, the sex organs appear normal, but sexual maturation does not occur. The joints show limited extensibility, particularly in the fingers. The appearance of the hands is characteristic (Fig. 368, B): the breadth is greater than the length; the fingers are maintained in a "clawing" position, and the fourth and fifth fingers are incurved. Coxa valga and genu valgum of a moderate degree may be present. The combination of the clawlike hands, the large head, the grotesque, inhuman facies and deformed limbs accounts for the designation of "gargoylism." The thickness of the skin contributes to the characteristic picture. Corneal opacities and mental retardation occur in a large percentage of these children. In the white blood cells abnormal granulations (Reilly bodies) may be found, but laboratory studies show no other characteristic changes. Several atypical forms of this disorder have been described.

**Diagnosis.** The stunted growth, the thickness of the skin and the mental retardation suggest *cretinism*, but the laboratory data and the roentgenographic changes are adequate for differentiation. Roentgenograms show the sella turcica to be elongated in many cases. The changes of the spinal column are best seen in the lateral view. The vertebral bodies

are shortened in the sagittal direction, their anterior and posterior outlines appear concave, and the spinous processes are directed downward. The first or second lumbar vertebra is small and displaced backward, resulting in deformity of the spine (Fig. 369, A). The lower ribs are club-shaped. The humerus is long and thick, the ulna and radius short and thick; their epiphysial ends and their epiphyses have irregular outlines. The metacarpal bones are bottle-shaped, the basal phalanges cylindrical (Fig. 369, B). The femur, tibia and fibula are moderately thickened, and their epiphyses are angular.

The disproportionate shortness of the extremities of classic *chondrodystrophy* is absent in gargoylism. The deformities of the head, the appearance of the hands and the mental retardation distinguish this disorder from *Morquio's disease*.

**Prognosis and Treatment.** The prognosis is unfavorable, since the patients remain retarded in mental and physical development. Orthopedic treatment may aid in correcting the deformity of the spine.

### OSTEOPETROSIS

(OSTEOSCLEROSIS FRAGILIS, ALBERS-SCHÖNBERG'S DISEASE)

Osteopetrosis is a rare disorder characterized by hardness and brittleness of the bones.

FIG. 370. Osteopetrosis of skull, pelvis and femurs.

**Etiology.** In the majority of cases the mode of inheritance appears to be recessive; in some cases, dominant. Males and females are equally affected.

**Pathology.** The cortex of the bones, as well as the trabeculae, is thickened. The endochondral ossification is disturbed by lack of resorption of cartilaginous intercellular ground substance. Islands of this partly calcified ground substance, which under normal conditions is replaced by bone, persist and are found in the shafts of the bones. The trabeculae are unusually crowded and numerous. At the ends of the long bones, as well as in the scapulas and pelvic bones, zones of increased and decreased density alternate. The zones of decreased density consist of areas of bone marrow. In the dense parts of the shaft the marrow spaces are reduced in volume; the marrow may contain abnormal cells or may undergo fibrous changes. In the mem-

branous bones the trabeculae are also densely arranged and thickened. The foramina for the cranial nerves are often constricted by an overgrowth of bone. The chemical composition of the bones is normal.

**Clinical Manifestations.** This condition probably always begins in utero, although clinical symptoms may be absent in infancy. Brittleness predisposes the bones to fracture, and roentgenograms taken on occasion of a fracture often reveal the underlying process for the first time. Although the fractures as a rule heal satisfactorily, deformities frequently develop during childhood. The head is square and somewhat enlarged, and deformities of the chest and spine may be present. Vision is usually disturbed early in life and diminishes progressively; the movements of the eyes may be impaired. Cataracts and optic atrophy may develop. A progressive deafness has frequently been described. The teeth develop abnormally and have a tendency to decay. The patient often has a hypochromic anemia and, in the final stage of the disease, a myelophthisic one. Hepatosplenomegaly and enlargement of the lymph nodes have been observed. Osteomyelitis is a frequent complication, particularly in the mandible or maxilla. General growth is retarded, and some of the patients are dwarfed. The mentality is normal, but chronic illness, blindness or deafness may interfere with its development.

**Diagnosis.** Roentgenographic demonstration of increased density of the entire skeleton is the essential feature and is diagnostic. No distinction can be made between the cortex and marrow. There are heavy shadows at the base of the skull, the bones of the vault appearing less dense (Fig. 370). The long bones, particularly the femur and tibia, are club-shaped, and transverse bands are seen near their ends. Similar bandlike stratification may be found in the os ilium and in the scapula, where they run parallel with the outlines of the bones. Skeletal maturation is normal.

Localized sclerotic processes as seen in *siphilis* and *sclerosing osteitis* are easily distinguished from osteopetrosis. A generalized *osteosclerosis* may result from fluorine poisoning, but in such cases calcification of muscles and ligaments is also often present.

**Prognosis and Treatment.** The prognosis is unfavorable in the majority of cases observed during childhood. Accidental detection of osteopetrosis in a number of apparently healthy adults is evidence that the

disorder may exist for a long time without causing significant symptoms.

There is no treatment. The complications are treated symptomatically.

## OSTEOGENESIS IMPERFECTA

This disease is characterized by increased fragility of the bones, which are easily fractured by slight trauma. Patients suffering from this disorder usually have blue scleras and flaccid ligaments; some of them become deaf later in life.

In severe cases fractures occur in utero, and the infant is born with deformities (*osteogenesis imperfecta congenita*). In other instances fractures do not occur until several years after birth, and the tendency to break bones easily disappears after puberty (*osteopsathyrosis*, *osteogenesis imperfecta tarda*). This latter form usually has a milder course, but often occurs repeatedly in the same family or sibship. Whether the two forms are identical is a matter of dispute.

**Etiology.** The disorder is determined before birth. Osteopsathyrosis is often transmitted as a dominant hereditary trait, but the different manifestations (blue scleras, fragility of the bones, deafness, and the like) may be dissociated in various members of the family (p. 237). The congenital form is usually not familial, although rarely it may alternate with the late form (osteopsathyrosis). Whether the congenital cases are nonhereditary (phenocopies) or hereditary on a recessive basis has not been determined.

**Pathology.** Osteogenesis imperfecta is a systemic disease in which a defect of the mesenchyma and of some of its derivatives (scleras, bones and ligaments) is considered responsible for the various symptoms.

The cortex is invariably diminished in thickness, owing to the disturbed formation of periosteal bone. Inactivity of the patient contributes to the atrophy of the bones. Osteoblastic activity is defective, and the osteoid and mature bone are of fetal quality. The generalized mesenchymal involvement in the congenital form of the disease is demonstrable in sections of the skin and scleras by a failure of the reticulum to differentiate into mature collagen. In some cases the abnormally thin scleras allow the underlying pigment to show through. In others increased transparency, but not thinness, of the sclera is observed. Occasionally cataract, coloboma and embryotoxon are associated with this disorder. Deaf-

ness may be due to otosclerosis or labyrinthine disturbance.

**Clinical Manifestations.** In *osteogenesis imperfecta congenita* fractures may occur early in utero, and the infant is born with deformed extremities, since the bones generally heal in abnormal positions. Fractures also occur frequently during the process of delivery. The skull has wide membranous spaces between the bones of the vault, and crackling is often felt on pressure. Many wormian bones are found within the occipital, parietal and temporal bones (Fig. 371, A). The eyes are often prominent, the scleras blue. The neck is short. The chest and the spine are deformed in severe cases. Many children with the severe congenital form die soon after birth. In those who survive, fractures of the extremities may result from otherwise inconsequential trauma. Callus usually forms rapidly, and the process of healing is considered satisfactory. The callus, however, is often replaced by inferior and rarefied bone which is prone to bend and breaks easily. Most of the fractures occur in the legs, where bizarre deformities develop (Fig. 372). Many patients with osteogenesis imperfecta are unable to learn to walk, since every attempt to stand or walk results in fractures.

The levels of calcium and phosphorus in the blood serum are normal.

In *osteopsathyrosis* (*osteogenesis imperfecta tarda*) the child appears normal at birth, and fractures usually do not occur until after the first year of life. There is great variation in the time of the first fracture. Occasionally osteopsathyrosis is so severe that it resembles the congenital form in the development of early and numerous fractures. In the majority of instances, however, only a moderate number of fractures occurs, and the fragility ceases with puberty. The bones of the extremities are long and slender (Fig. 373, A); 70 per cent of the fractures are in the lower extremities. Healing takes place rapidly, but deformities may develop. As a rule all the affected members of a family can be recognized by their blue scleras. Only about two thirds of the members with blue scleras suffer from increased fragility of the bones, and only about one fourth from deafness. The flaccidity of the ligaments and muscles may result in repeated dislocations. Deafness is usually a late manifestation and hence is rarely found in children.

A clear distinction between osteogenesis imperfecta congenita and tarda cannot always

FIG. 371. Osteogenesis imperfecta. A, Skull showing wormian bones. B, Roentgenogram of lower extremity at birth. C, Roentgenogram of lower extremities at 5 years of age.

FIG. 372. Osteogenesis imperfecta in a 5-year-old girl.

be made, and intermediate forms may be encountered.

**Diagnosis.** In roentgenograms of the newborn infant the unbroken bones in *osteogenesis imperfecta congenita* are thin, but otherwise appear normal. The previously fractured bones appear irregularly thickened, curved or angulated (Fig. 373, B); the epiphysial ends

are usually normal. The skull is characterized by thinness of the bones and by the osseous islands, the wormian bones, which are separated from each other by numerous sutures of irregular shape. The mineral content of the bones seems reduced, but the bone age corresponds to the child's chronologic age. As the child grows older and the processes of

fracturing and healing continue, the shafts of the bones assume grotesque shapes.

In *osteopsathyrosis* roentgenograms show the unbroken long bones to be slender and elongated. Their epiphyses are normal. Improper healing of fractures may result in deformities; demineralized areas are frequent.

*Syphilis* may be suspected in the newborn infant if the movements of the extremities are limited and painful. However, the destructive processes in the metaphysis frequently present in syphilis are absent in osteogenesis imperfecta. *Chondrodystrophy* and osteogenesis imperfecta result in micromelia, but otherwise the two disorders have little in common. In the former the bones are thick and short, and the epiphysal ends are irregular. The epiphysal changes in *rickets* are an adequate distinguishing factor. The diagnoses of osteogenesis imperfecta and of osteopsathyrosis are facilitated by the presence of blue scleras; and in osteopsathyrosis a typical family history is often obtained. *Hypophosphatasia* in the newborn may resemble osteogenesis imperfecta congenita, but is readily distinguished (p. 1224) by the low serum phosphatase values and by fraying of the ends of the bones.

**Prognosis and Treatment.** Many children with *osteogenesis imperfecta* are stillborn or die soon after birth. Those who survive usually become severely deformed.

Children with the late form, *osteopsathyrosis*, may also become deformed, but the deformities can be lessened by orthopedic treatment. Frequently they can live fairly normal

lives. The prospect of developing deafness and of transmitting the disorder to part of their offspring, however, must be considered in relation to the prognosis.

No effective treatment is known for osteogenesis imperfecta. Good nutrition and correct treatment for the fractures are essential. Vitamin D should be given in usual amounts, but massive doses may be harmful.

FIG. 373. Osteopsathyrosis.

## MISCELLANEOUS DISORDERS

### ARACHNODACTYLY

(DOLICHOSTENOMELIA, MARFAN'S SYNDROME)

Arachnodactyly, abnormal length of the extremities, particularly of the fingers and toes, represents a congenital anomaly which is frequently combined with luxation of the lens (Marfan's syndrome) and other malformations.

**Etiology.** The disorder is considered a general "mesodermal dystrophy." In many families the syndrome is inherited as a dominant trait, but there are sporadic cases in which the etiology is doubtful.

**Clinical Manifestations.** The patients tend to be tall and underweight, and their extremities are long and thin (Fig. 374). The

fingers are characterized by the term "spider-fingers." The phalanges, metacarpals and metatarsals are unusually long. The muscles are usually flaccid, so that the joints are hyperextensible, but occasionally the syndrome is combined with arthrogryposis. The skull is long and narrow, the palate high. The external ears are frequently deformed. Luxation of the lens may be combined with cataract, megalocornea, coloboma and other defects of the eye. Myopia, strabismus and nystagmus are frequently present. The spine sometimes shows scoliosis and kyphosis. Deformities of the chest and cardiovascular disease develop as the children grow older. Cardiac hypertrophy, valvular deformities, aortic cystic medionecrosis, aortic aneurysm (sometimes dissecting) and other anomalies

FIG. 374. Arachnodactyly.

have been found at autopsy. Imperfect lobation of the lungs, renal ectopy, dislocation of the hips and other malformations are also occasionally associated with the syndrome. The mentality is normal in the majority of instances.

**Prognosis and Treatment.** The patients have a tendency to respiratory disease, but the prognosis depends chiefly upon the cardiac lesions. Some children reach maturity and transmit the disorder to some of their children.

Appropriate treatment of the deformities of the spine and of the eye defects is required.

## MULTIPLE EXOSTOSES

(DIAPHYSIAL ACLASIS, DYSCHONDROPLASIA, ECCHONDROSIS OSSIFICANS)

In this disorder hard, irregular prominences appear in the region of the metaphyses of bones. The condition is hereditary in the majority of instances, a dominant mode of transmission being the rule. If a person appears to be "skipped" in a pedigree, roentgenographic examination may reveal small exostoses which have escaped external inspection. A sporadic instance may represent a

phenocopy or a member of a sibship in which the disorder had not been noticed before. Males are affected more often than females.

**Pathology.** The exostoses consist of spongy bone covered by a layer of compact bone and a shell of hyaline cartilage. The excrescence enlarges by endochondral, periosteal and perichondral ossification. Exostoses develop only on parts of the skeleton previously cartilaginous. They develop from intraperiosteal or subcortical cartilaginous rests, whereas the enchondromas sometimes associated with them arise from cartilaginous islands situated in the spongiosa. Exostoses occur chiefly on the long bones, but occasionally the base of the skull, the vertebral column, the ribs, the scapulas and the pelvis are affected. The growth of exostoses stops when general growth of the skeleton ceases.

**Clinical Manifestations.** Although exostoses are frequently present at birth, they are usually not noticed before the second year of life, when osseous elevations become prominent near the ends of bones. Growth of the affected bones is retarded, and deformities may develop. The radius is often longer than the ulna and bends around the end of this bone, resulting in ulnar deviation of the entire hand. Genu valgum and pes planus frequently develop. Metaphysial enlargement may be seen in the fingers and toes, and functional disturbances may be present. The exostoses are usually bilateral and often symmetrical. Occasionally a large osteochondroma develops from an exostosis; it may interfere with free movements of the limbs or press on nerves or blood vessels (Fig. 375, B).

**Diagnosis.** On the roentgenogram exostoses appear as small or large spurs or as pedunculated, truffle-shaped excrescences (Fig. 375, A). They originate within the metaphysis and always grow away from the epiphysis. The structure of the entire metaphysis is abnormal; the irregular ossification is indicated by rarefied areas in which striation or abnormal trabeculation can be seen. Exostoses frequently cause curving of the affected or neighboring bones, and the spaces between radius and ulna and between tibia and fibula are often enlarged.

Osteochondromas have been mistaken for malignant tumors; exostoses in other parts of the skeleton suggest the benign state of the tumor. When there is doubt, a biopsy should be obtained.

**Prognosis and Treatment.** Exostoses and the osteochondromas developing from them are not malignant; rarely they may be trans-

FIG. 375. A, Exostoses of both femors. B, Osteochondroma in the fibula of the same patient.

formed into chondrosarcomas. Exostoses and osteochondromas become quiescent when growth of the patient is complete. Surgical intervention may be required for limitation of movement or for the relief of pressure symptoms on nerves or blood vessels.

### OLLIER'S DISEASE

(CHONDRODYSPLASIA, DYSCHONDROPLASIA)

This malformation of the ends of the shafts is characterized by the presence of nonossified cartilage in the diaphysial ends of bones. The disorder is usually unilateral, but occasionally lesser changes of the same sort are found on the opposite side. Since facial asymmetry is often present, a relationship to hemiatrophy seems probable. There is no evidence that this disorder is genetically determined.

**Pathology.** The cartilaginous islands consist of hyaline cartilage upon which bone is deposited. The cells are larger and more irregularly distributed than in normal epiphyseal cartilage. The cartilage is calcified in parts of its periphery, but it does not ossify normally.

**Clinical Manifestations.** There is a gradual onset of symptoms during the first few years of life. It may be noticed that one limb is shorter than the other, or an external

deformity may appear near a joint. In many cases the disease affects the arm and the leg of the same side, and the pelvic and facial bones may also be involved. There may be deformity, shortening of the limbs and limitation of movement. The process as such is not painful, but use of the deformed extremities may cause discomfort.

**Diagnosis.** The disorder is easily recognized when the lesions are unilateral. In the roentgenogram the upper end of the humerus appears thickened; the cortex of the diaphysis is defective; rarefaction is seen in the interior of the bone. The distal ends of the radius and ulna show similar defects at times; the epiphyses are also affected (Fig. 376). The central parts of the shafts are not rarefied, but the shafts may be shortened and thickened. An abnormal bony structure is sometimes found in the acromial end of the scapula and in the pelvic bones of the affected side. In the proximal and distal ends of the femur and tibia there are areas of rarefaction through which dense lines pass either parallel or obliquely to the long axes of the bones. The affected diaphyses may stand at an angle to the center of the shaft and thus contribute to the deformity of the limb.

Isolated lesions may resemble those of *sypilis* or *leukemia*, but the unilateral involvement and absence of other diagnostic

FIG. 376. Humerus and forearm in Ollier's disease.

features of these two diseases suffice for differentiation. Intrametaphysal areas of rarefaction in bones with *multiple exostoses* may resemble Ollier's disease, but the bilateral occurrence of exostoses permits differentiation.

**Prognosis and Treatment.** The process is not progressive, but shortening becomes manifest as the rest of the body increases in size. Infrequently sarcoma has developed in an affected bone. Fractures may occur in the rarefied areas. Orthopedic treatment for the correction of malformations and the prevention of further deformities is indicated.

## MELORHEOSTOSIS

(LÉRI)

This skeletal disorder is a form of hyperostosis which begins in infancy or childhood and progresses slowly on one side of the bones of a single extremity; for example, from the shoulder to the fingers or from the hip to the toes. Thus in the arm the ulnar side may be affected and the radial side remain normal. Enlargement, swelling and curving of the fingers or toes and deformity of the proximal bones of the same limb are clinical manifestations. Roentgenograms reveal a characteristic hyperostosis limited to one side of the bone. Melorheostosis is probably a developmental disorder, but infection and disturb-

ance of sympathetic vasomotor control have also been considered etiologic factors.

## FIBROUS DYSPLASIA OF BONE

(OSTEITIS FIBROSA DISSEMINATA, POLYOSTOTIC FIBROUS DYSPLASIA, OSTEODYSTROPHIA FIBROSA)

Osseous fibrous dysplasia may affect one or many bones of the skeleton. In polyostotic cases the distribution tends to be unilateral; if both sides are involved, one side is affected more than the other. Fibrous dysplasia is probably due to a developmental error of early embryonic life, but there is no proof that the disorder is hereditary. The lesion consists of a fibrous matrix studded with trabeculae of immature bone with varying degrees of calcification. Monostotic cases may be free of symptoms or show only a local swelling. Sometimes a fracture, pain or functional impairment leads to recognition of the disease. If several bones of a limb are affected, clinical complaints are more frequent, and bowing and fractures are common manifestations. Flat bones sometimes become distended into tumor-like masses, while long bones become shortened, curved and thickened. Roentgenographic changes consist in diffuse and cystic osteoporosis, sclerosis, evidence of fractures and abnormal outlines of the bones (Fig. 377). In the severest form of the disease several limbs may be involved, and the skull, vertebral column and pelvis may be included in the pathologic process. In such cases the osseous changes are often associated with brown pigmentation of the skin and with precocious osseous development and precocious puberty, which is seen more often in girls than in boys (McCune-Albright's syndrome) (p. 1159). The blood calcium and phosphorus are normal, but the serum phosphatase is elevated.

## LEONTIASIS OSSEA

In this disease there is an overgrowth of the facial and cranial bones. A few cases have been reported with involvement of the long bones, but most often the disorder is limited to the face and cranium. Leontiasis ossea is probably not an etiologic entity, but a syndrome which may occur in various osseous disorders.

It usually begins insidiously in childhood or early adult life and gives rise to a diversity of symptoms. The skull may increase symmetrically in size, or there may be one or

FIG. 377. Osteitis fibrosa disseminata. Roentgenogram showing extensive fibrous dysplasia of the sacrum, left ilium and femur. Note the irregular demineralization and expansion of the cortex. (Stauffer, Arbuckle and Aegerter: *J. Bone & Joint Surg.*, Vol. 23.)

more prominences. Headache, most severe in the involved part of the skull, is usually the first complaint. Eye symptoms may include exophthalmos, epiphora and optic atrophy. Facial paralysis may result from pressure on the seventh nerve; nasal obstruction from bony overgrowth is common. Convulsions with or without paralysis have been described.

### MANDIBULOFACIAL DYSOSTOSIS

(TREACHER-COLLINS SYNDROME)

The chief manifestations of this syndrome are abnormal (antimongoloid) position of the palpebral fissures, coloboma in the outer portion of the lower lids, hypoplasia of the malar and of other facial bones, malformations of the ears, macrostomia, high palate, blind fistulas opening between the angles of the mouth and the ears and atypical hair growth extending towards the cheeks. Facial clefts, diseases of the ears and deafness occur often in affected persons. The syndrome is often incomplete. The disorder is hereditary and transmitted as a dominant trait attributed to a pleiotropic gene. In many cases the expressivity is reduced.

### ARTHROGRYPOSIS

The term "arthrogryposis" denotes congenital contraction of joints in flexion. It may occur

as a clinical entity or be associated with other malformations such as arachnodactyly and premature synostoses of the bones of the skull (p. 1243).

**Pathology.** The pathologic changes involve thick, inelastic articular capsules and atrophic muscle fibers with some fibrosis and fatty infiltration. Degeneration in the cells of the anterior and posterior horns of the spinal cord with thickening and increased vascularity of the meninges has been reported, but the relationship to the lesions in and about the joints has not been established.

**Clinical Forms.** *Arthrogryposis multiplex congenita* is the term for a special form of this disorder in which there is a congenital stiffness of one or more joints associated with a hypoplasia of the attached muscles. It is the result of incomplete fibrous ankylosis. Dislocation of the hips and of other joints occurs frequently in children with this disorder. Since ankylosis of some joints occurs in extension, the term "arthrogryposis" is not entirely justified, and *multiple congenital articular rigidities*, a name also used, is more adequate. The disorder has been attributed to prolonged intrauterine pressure, but the frequent association with malformations such as defects of the palate, vertebrae, and absence of the sacrum and fibula indicates origin early in

embryonic life before intrauterine pressure becomes a teratogenic factor.

**Clinical Manifestations.** The disorder appears sporadically, but two cases in one family have been observed. The arms are rotated inward; the thighs, outward. The elbows and knees, which are described as cylindrical, are usually ankylosed in extension, although fixation of the knees in flexion also occurs. The wrists and the fingers are flexed, and clubfeet are present. Certain muscle groups may be underdeveloped or absent (amyoplasia congenita). The skin appears thickened, and there may be dimples in the skin near the joints. Roentgenograms show only atrophy of the bones.

**Treatment.** Treatment consists in massage, passive movements, gradual correction of deformities by splints and plaster casts, and orthopedic surgery. According to Chapple, intermittent treatment with a combination of progesterone and an estrogenic substance has been effective in relaxing the joints in some instances.

## HEMIHYPERTROPHY

In hemihypertrophy, a congenital malformation, one side of the body is larger than the other (Fig. 378).

**Etiology.** The most credible explanation of this malformation is a faulty cell division of the zygote resulting in two daughter cells of unequal size; it has been considered a form of incomplete twinning. Females are more often affected than males; the right side of the body, more frequently than the left.

**Clinical Manifestations.** The difference in the two sides is usually greatest in the extremities, the genitals and the trunk. Facial and palatal inequality may also be present. The paired internal organs are sometimes of unequal size. In true hemihypertrophy the bones of the larger side are longer and thicker than the corresponding ones of the other side. There may also be a difference in maturation as seen in the development of the centers of ossification in roentgenograms. There may be associated malformations such as polydactyly, hypospadias, cryptorchism, nevi and hemangiomas. Rare instances of association with tumors or calcification of the adrenal gland have been reported. The mentality may be normal, but retarded development has been observed.

**Differential Diagnosis.** Differentiation from *hemiatrophy* may be difficult, but hemiatrophy is frequently associated with such

FIG. 378. Hemihypertrophy in a girl 4 years of age. The hypertrophy was of the entire left side of the body, including the face, teeth and tongue.

nervous symptoms as paralysis and athetosis. A congenital arteriovenous fistula may result in overgrowth of one extremity, and a similar effect can be caused by a low grade nondestructive infection near an epiphysis. In *Milroy's disease* the soft tissues only are involved.

**Prognosis and Treatment.** The differences in the two sides often become less as the child grows older. Treatment is symptomatic; orthopedic corrections should be instituted early in life.

## HYPERTROPHIC PULMONARY OSTEOARTHROPATHY

This condition, sometimes termed "Marie-Bamberger disease" or "hippocratic fingers," occurs in association with chronic pulmonary conditions and with congenital cyanotic heart disease. The lesions are an ossifying periostitis, effusion into the joints, erosion of the cartilages and hypertrophy of the soft tissues. In mild cases there is only clubbing of the fingers, the nails being broad and curved both transversely and longitudinally. In well developed cases there is also enlargement of the ends of the long bones and of the hands and feet, with pain and swelling of the joints. Clubbing of the fingers does not appear until several weeks to a year or longer after development of the causative disease.

A hereditary type of clubbing of the fingers,

not dependent upon circulatory or pulmonary disease, has been described.

# ORTHOPEDIC PEDIATRICS

## RESPONSE OF BONE TO LOCAL AND GENERAL DISTURBANCES

Bones are living tissues composed of constantly changing molecules. They are not solid substances of inert matter, but are alive, responsive and changeable. "Tagged" calcium molecules in a particular bone at the time of one examination may be in another bone at a subsequent examination or may have been excreted.

Careful photoelectric comparisons of roentgenograms have been reported by Mack to reveal measurable changes in density after a starvation period of only a few days, and discernible change during short illness and with variations of exercise or bed rest. Perhaps bone would remain relatively constant in its component molecules, and perhaps a certain calcium molecule deposited in bone would remain stationary for an indefinite time, if its environmental conditions were not changed. But they are changing continuously, even in the normal person, and these changes are accentuated during infectious and metabolic diseases and starvation.

The structure of bone can be changed also by alteration of mechanical stresses upon the bone or of its blood supply.

Bone may overgrow in length and in diaphysial diameter as a result of such different causes as hemangiomas, venous obstruction and lymphatic blockage; failure to grow adequately in diameter may be a result of curtailment of passive activity.

## RELATION OF INTRAUTERINE POSITION TO ORTHOPEDIC DISTURBANCES

Congenital malformations are discussed on page 1226.

Different etiologic factors can be responsible for identical structural defects in the fetus. Thus cleft palate in the rat may be genetic in origin or may be an environmental congenital defect resulting from infection, poisoning or vitamin deficiencies in the pregnant rat. It may also be that intrauterine posture can produce the same deformity. The "position of comfort" of the newborn with severe brachygnathia suggests that this may be the case. When the mandible is extremely small or posteriorly subluxated, it is commonly

accompanied by cleft palate. The tongue, which is rarely, if ever, proportionately small, must be accommodated in the nasopharynx, since the mouth does not provide ample space for it. Additional suggestive evidence is supplied by prenatal roentgenograms of infants with brachygnathia showing their heads to be constantly flexed on their chests in utero.

**Intrauterine Postural Effects.** Normally the fetus floats freely for the first half of the gestational period. Until the midpoint of the second trimester it has had unimpeded movements. About this time it begins to impinge on the uterine wall, and the mother translates these collisions as "feeling life." The fetus continues to grow, but the amniotic fluid diminishes relatively in amount. During the latter half of gestation the fetus becomes increasingly restricted until it cannot extend any part without encountering the muscular wall. When it changes its position in relation to its mother, it is unable to alter its own posture.

In order to achieve maximal flexion, the fetus must have a minimum of tension in its stretched joint capsules. This degree of relaxation may be achieved by absorption of a "relaxing factor." After birth the infant retains excessive pliability for approximately the same length of time that other maternal hormonal influences are evident.

The intrauterine position can be reconstructed after birth by "folding" the infant into his most comfortable position. Infants who have been subjected to marked capsular stretch in the uterus are likely to be fretful in the unaccustomed position in which they find themselves after birth. When such an infant is "folded," his fretting ceases immediately, and he falls asleep in his "position of comfort."

To reconstruct the fetal posture, the infant's mouth should be inspected first, since asymmetry of the lips and an angulation of the mandible are among the most common minor abnormalities. These are caused by pressure of the chin against a shoulder when the head was flexed laterally. This position can be responsible for disturbances in respiration and/or swallowing through pressure on the recurrent or superior laryngeal vessels and nerves. These can be pinched between the cartilaginous and osseous structures in the

FIG. 379. A-1, The "position of comfort" of an infant with torticollis and deviated jaw, illustrating one mechanism by which these may be produced. The right sternocleidomastoid is elongated and has been thinned by the stretch (A-2), while the left remains contracted and short. A-3, An effect of pressure against the jaw, and (A-4) a position of the fetal head which can cause it.

B-1, B-2, Sitting on the feet in utero presses them against the soft buttocks. This produces no bony deformity, but causes a mild medial deviation of the feet (metatarsus varus). B-3, B-4, A thigh twisted to bring the knee across the body is difficult to release in utero. Breech deliveries result from this position and others from which the fetus cannot disengage itself.

C-1, The "position of comfort" when the normal release from embryonic cephalic flexion does not occur. C-2, Posture of C-1 in utero. C-3, Brachygnathia ("Andy Gumpism") resulting from this fetal position. The mandible may be pressed up or back and the larynx compressed. Pressure marks on the chest and an angulated manubrium are usual accompaniments. Dyspnea and stridor are among the symptoms. C-4, The gingival ridge is flattened and indented. Fascia is visible at the pressure points. The palate is almost entirely absent. When the forced position of the head prevents withdrawal of the tongue from between the palatal buds where it originated, the tongue develops within the nasopharynx.

D-1, Deformity can result when bone is forced against bone by uterine pressure. D-2, The fetal position by which this deformity (D-1) was caused. D-3, Prenatal roentgenogram of curvature of the fetal spine. D-4, The newborn infant, shown in utero in D-3, prefers to lie curved toward his right side, but, other than facial asymmetry from pressure against the uterine wall, he is normal.

neck if the head is immobilized in lateral flexion against the uterine wall. The face is weakened or paralyzed on the side exposed to the wall, and the laryngeal nerve and vessel are affected on the opposite side. The respiratory disturbances are those of laryngeal obstruction; the digestive ones are regurgitation, aspiration and air swallowing. The prognosis depends on the severity; in the common mild form the facial asymmetry and noisy breathing last only weeks to months.

When a foot has been maintained beside the head, it may be rounded and the over-straight leg may assume the "back-knee" position. In the milder forms this deformity is not unusual and can be demonstrated by passive hyperextension through the neonatal period. When the knee was hyperextended beyond 45 degrees, it may persist in such a position; and in the rare instances when hyperextension has been greater, there is likely to be an associated posterior dislocation of the hip.

Many fetuses are confined in a kneeling position with feet pressed against the buttocks. Occasionally the legs are crossed. The molding is severe when they are pressed against other bony parts, but is mild to negligible when they are pressed against soft parts.

"Positions of comfort" are of infinite variety. They include hands hyperflexed along the forearms or grooving the thorax, heads indented by an arm, heads hyperflexed against the sacrum, feet pressed tightly against the tibias, and many others. Reconstruction of the "position of comfort" frequently explains clubfeet, torticollis, dislocated elbows, and asymmetries, as well as other deformities (Fig. 379).

After the first week of life the relaxation diminishes rapidly but selectively. Muscles and joint capsules which were not stretched or strained during fetal life retain considerable pliancy throughout infancy, whereas those affected by fetal position become restricted in their range of motion. The jaw which was pressed against the sternum cannot be opened wide, and the thighs of an infant whose hip joint capsule was stretched cannot be abducted (p. 1254). In other stretched joints this stiffness is present for only a few months, but in the jaw and in the hips it may last longer. The muscles closing the mouth are stronger than those opening it, and those adducting the hip are stronger than those abducting it. In the stiffened jaw the attached muscles are limited in their exercise by the restricted movement of the mandible. In the

relaxed hip the muscles splint an unstable joint and continue to do so until ossification is established or dislocation occurs.

## THE FOOT

### NORMAL FOOT

The normal foot of the infant and young child appears grossly abnormal if judged by adult standards. The infant's foot is fatter and wider than that of the adult. It seldom has a distinct longitudinal arch and never a transverse one. Fat pads may create a fullness which suggests flatfoot. This is accentuated by the normally soft and pliable muscle of infants. The line of the Achilles tendon, straight in the adult foot, may be moderately angulated in the child, and the foot slightly everted.

### PRONATION OR FLATFOOT

The term *flatfoot* as applied to the infant most often indicates that the medial longitudinal arch does not *look* as high as the parents or physician would like to see it. In most children it is not an abnormality, requires no treatment and does not call for orthopedic corrective shoes.

To decide whether a foot is normal or abnormal requires examination of its component parts and evaluation of its functional status—not merely a casual inspection of the weight-bearing foot. If the child with the suspected "flatfoot" is asked to stand on his toes, a definite longitudinal arch will usually appear. Next the child is asked to stand on his heels with the front of the foot off the floor. If these two maneuvers are successfully accomplished, there is high probability that the feet are well within normal limits.

The joints are examined by checking their motions. The ankle joint moves in dorsiflexion and plantar flexion; the joints of the foot in eversion and inversion. After the physician has examined a few children with normal feet he will have learned the normal range of motion. The length of the heel cord must be tested with the knee straight and the foot inverted; then when the ankle is dorsiflexed, the lateral border of the foot should make an acute angle with the tibia of 80 degrees or less. A short heel cord is an indication for orthopedic examination and usually requires treatment.

The muscles which activate the joints are as follows: tibialis anticus, to produce dorsiflexion and inversion; tibialis posticus, to produce plantar flexion and inversion; perone-

us tertius, to produce dorsiflexion and eversion; peroneus longus and brevis, to produce plantar flexion and eversion; and gastrocnemius and soleus, to produce plantar flexion. The child should carry out each of these motions actively, and the strength of the muscles should be tested. The strength of extension and flexion at the metatarsophalangeal joints should be carefully examined, since the integrity of the anterior arch depends on the flexibility of these joints.

The dorsalis pedis and posterior tibial pulses are palpated, and the tendo achilles and plantar reflexes tested. Sensation is checked on the dorsal and plantar surfaces.

If this systematic examination reveals no abnormalities, the feet are "normal," and no treatment for the "flatfoot" is required. Specifically, so-called orthopedic shoes with Thomas heels are not indicated.

Occasionally a child will complain of pain or fatigue in the feet after play, and neither the examination described nor a roentgenographic examination of the foot will reveal any abnormality. Foot strain is the usual cause of such complaints, and exercises to improve the tone of the muscles supporting the foot are indicated. The young child should be instructed to walk "tip-toe" for five to ten minutes daily; the older one, to stand slightly pigeon-toed with the weight thrown on the lateral border of the foot for five to ten minutes daily. Mechanical support for the arch is not required and is contraindicated in the absence of abnormal findings.

#### PIGEON TOE

Pigeon toe is a frequent presenting complaint. There are three common causes for toeing-in. Metatarsus adductus is the most common of the congenital foot deformities. It consists in adduction of the forefoot with no deformity of the hindfoot. Treatment is required as early as possible and before the infant walks. The deformity is easily corrected by passive stretching, reverse shoe, or casts and wedging, depending on its severity. There is rarely a tendency for it to recur, as is the case with congenital clubfoot. It is frequently associated with congenital dysplasia of the hip, and careful examination of the hip is mandatory.

The second most common cause of pigeon toe is inward tibial torsion. A line drawn from the anterior-superior iliac spine through the center of the patella normally intersects the second toe when the forefoot is neither

abducted nor adducted. In tibial torsion this line intersects the fourth or fifth toe or a point lateral to the fifth one. Tibial torsion is always associated with a tibial bow. The condition requires no treatment such as braces, bars or shoe wedging, but is corrected as the extremity grows. Tibial torsion is frequently associated with metatarsus adductus. When this is the case, the latter should be corrected as described above, but it should be recognized that the pigeon toe will persist until growth has corrected the tibial torsion. The pigeon toe will subsequently be self-corrected.

The third cause of pigeon toe is inward femoral torsion. For examination the child is placed supine, the legs inwardly rotated and then outwardly rotated at the hips. Normally, inward rotation is about 30 degrees and outward rotation 60 degrees. In inward femoral torsion the inward rotation will approach 90 degrees, the patellae will face each other, and outward rotation is practically nonexistent. This condition requires no treatment and is corrected spontaneously during growth.

#### CLUBFOOT

The so-called primary type of congenital clubfoot is exceedingly rare and results from absence of muscles or bones or of fusion of bones. Correction is by orthopedic means.

The usual congenital clubfoot is a secondary deformity of the foot and ankle. The most frequent deformity is that of equinovarus, in which the foot is in plantar flexion and deviates medially. More than 95 per cent of congenital clubfeet are of the equinovarus type. Next most frequent is the deformity of calcaneovalgus, in which the foot is dorsiflexed and deviated laterally. Many children are born with the positional abnormality of equinovarus or calcaneovalgus. If the foot can be passively brought into the opposite position, the infant does not have a clubfoot and requires only simple exercises for correction of the deformity. *The foot which cannot be passively overcorrected is a clubfoot and requires orthopedic treatment.* Conservative treatment with casts and wedgings or the Denis-Browne splint is preferred. Forcible manipulation and surgery are usually unnecessary.

#### SHOES

Before walking, it is unnecessary for an infant to wear shoes; and, while walking is limited

to carpeted floors, the shoes should be the softest obtainable, usually of the moccasin type. Later, when the feet need protection against the pounding received on hard floors and pavements, thicker soles become desirable. These should be as pliable as possible, since stiff-soled shoes limit the range of foot motion and therefore impede development of the supporting muscle. Orthopedic shoes are especially stiff and, on this account, should not be used.

## THE LEG

### BOWLEG AND KNOCK KNEES

Bowleg and knock knees are usually developmental variants and, if acquired lesions—such as rickets—and primary congenital abnormalities—such as achondroplasia—can be ruled out, they must be considered such even though the apparent deformity is marked. Furthermore, it can be expected that they will be corrected by growth within the limits of the heredity pattern. Wedges in the shoes have no effect on bowleg or knock knee.

FIG. 380. Blount's disease. The medial aspect of the proximal end of the left tibia is irregular and "beaked." There is also minimal involvement of medial aspects of the proximal tibial epiphysal center. As a consequence of the proximal tibial deformity, there was abnormal weight bearing, which in turn was responsible for the thickening shown in the medial cortex of the left tibia. The right tibia is normal.

Braces are used only in deformities in which the collateral ligaments of the knees are becoming stretched; they do not correct the deformity and are used only to prevent further relaxation of ligaments.

In developmental bowleg a record of serial measurements between the knees may be kept; in knock knees between the medial malleoli; or, in either, tracings of the legs can be made on wrapping paper to follow the progress of correction by growth. Correction of the deformity may be expected within a year or two in the average case.

*Blount's disease* is an acquired lesion of the upper tibial metaphysis at its medial aspect and may cause bowleg. The lesion may be unilateral or bilateral. It is thought to belong in the category of osteochondroses. Roentgenographically there is a roughening of the medial aspect of the tibial epiphysal center and of the medial aspect of the metaphysis with a beaklike projection. The leg should be braced until the lesion is healed, when osteotomy is usually required to correct the deformity.

### CONGENITAL GENU RECURVATUM

Hyperextension of the knee is not unusual in the newborn period and apparently is a result of positioning in utero. This deformity usually is corrected spontaneously within the first few months of life. Those that persist for more than several months require splinting in slight flexion to permit shortening of the posterior capsule of the knee joint.

## THE HIP

### CONGENITAL DYSPLASIA OR SUBLUXATION OF THE HIP

The infant with dysplasia of the hip only rarely is born with a frank dislocation of the joint. The head of the femur is usually only part way out of the acetabulum, which is more shallow than normal. If the condition is not diagnosed and treated, the joint may become normal; it may remain subluxated throughout life and lead to a degenerative arthritis in later life, or it may go on to a frank dislocation.

The diagnostic signs in early infancy are (1) a persistent limitation of abduction of the hip (Fig. 381): this is the first, the most reliable and often the only sign present as late as one month of age. Knees normally can be abducted more than 45 degrees from the perpendicular, which can be established by the median raphe or vulva. (2) Ortolani's

FIG. 381. Limitation of abduction is an early sign of congenital dysplasia of the hip.

FIG. 382. The Fredjka abduction splint for treatment of congenital dysplasia of the hip. The splint is discontinued when roentgen and clinical studies demonstrate ossification of the acetabular roof and a stable hip joint. Use of the splint is usually required for several months. (Vernon L. Hart: *Congenital Dysplasia of the Hip Joint and Sequelae*. Springfield, Ill., Charles C Thomas.)

jerk of entry or exit: each hip is tested separately. The hips are flexed to 90 degrees, and the hip to be tested is then adducted slowly with slight downward pressure on the knee. A click and a noticeable jerk may be heard and felt as the femoral head moves out of the acetabulum. The thigh is then abducted slowly to its maximum; a click and a slight jerk are noted as the head re-enters the acetabulum. (3) In a true anteroposterior roentgenogram of the pelvis the acetabular roof may be more oblique than that of the opposite side, or the metaphysis of the neck of the femur may be placed more laterally than that of the opposite side with widening of the space between the metaphysis and the acetabulum. Apparently normal roentgenographic findings do not exclude dysplasia of the hip during the first month or two of life. In unusual instances none of the signs described above may be present in the first

two months or so of life (they are usually evident by the first month). Thus it is imperative that the monthly examinations of the apparently healthy young infant should always include tests of hip function.

If any of these signs is present, the child should be treated immediately for congenital dysplasia. Treatment consists simply in maintaining the hips continuously in abduction until the subluxation has been corrected. The constant pressure of the head of the femur in the center of the acetabulum causes it to deepen. This abduction may be maintained in one of several ways; a stiff shell (Fredjka splint, Fig. 382) is effective. It is preferable to treat a normal hip occasionally than to fail to treat an abnormal one, since delay in treatment may permit the hip to dislocate, in which case treatment is prolonged and less certain to produce a normal hip. The use of casts is not recommended when treatment is started early in the first few months of age, since the incidence of Perthes' disease in infants so treated is relatively high.

When complete dislocation of the hip is present, the principal signs are shortening of the affected leg, limitation of abduction, limp if the child is walking and Trendelenburg's sign. (When the child stands upon the dislocated leg and raises the other foot from the floor, the pelvis on the normal side drops.) Excessive mobility of the joint is demonstrable when traction is applied to one leg—so-called telescoping. The roentgenogram demonstrates lateral and upward displacement of the proximal end of the femur in relation to the acetabulum. Appearance of the ossification center of the head of the femur is delayed; it will be smaller than that of the normal side. When there is bilateral dislocation, there is a waddling gait and lordosis.

Treatment requires reduction and immobilization in a plaster cast for six to nine months.

FIG. 383. Bilateral congenital dysplasia of the hip. A, At 2½ months of age the bony roof of each acetabulum is steep, and the left femur is displaced slightly laterally. B, At 10 months of age the left acetabulum is shallow, and there is definite displacement of the left femur laterally and superiorly; clinically there was no apparent shortening of the leg at this time. The left femoral capital epiphysis is smaller than the right. C, At 20 months of age the left hip has a more normal appearance, and at 17 years (D) there is no significant abnormality and both hips were functionally normal. Treatment consisted in maintained abduction until 8 months of age. After this, motion was permitted. No casts were used.

#### ACQUIRED DISEASES OF THE HIP

A variety of lesions of the hip, especially in their initial stage, may produce similar symptoms. These include trauma, acute and chronic (tuberculosis, see p. 1262), infections, Perthes' disease and slipped epiphysis. The common presenting symptoms are those of *synovitis*: limp and pain in the hip, or more often the pain is referred to the knee.

*Infection* is usually manifest systemically by fever and signs of toxemia, as well as by such local signs as muscle spasm and tenderness and pain on attempted passive motion of the joint. In infants the local and systemic signs of infection are difficult to interpret, and paracentesis should be performed whenever the possibility of infection is present. Acute suppurative synovitis is not uncommon, and its possibility must be kept in mind, particularly in the infant with acute cutaneous infections which may serve as the source of the bacteremia. (See Infectious Arthritis, p. 1259.)

*Trauma* is the most frequent cause of suddenly acquired limp and pain in the hip or knee (synovitis of the hip) which brings the child to the physician. Often the trauma has been so slight that it was overlooked or perhaps never known to the parents. A few hours later the joint is full of fluid and painful.

Examination may reveal limitation of motion, muscle spasm and swelling of the joint.

FIG. 384. Untreated congenital dislocation of the right hip demonstrating superior and lateral displacement of the underdeveloped femoral head and capital epiphysis, underdevelopment of the acetabulum and an increase in the slope of the acetabular roof.

The hip is a ball-and-socket joint, and its motions are tested in three planes: flexion and extension, abduction and adduction, and inward and outward rotation. These motions are compared with those of the normal side. In limitation of motion caused by muscle spasm the range of motion gradually increases as gentle pressure is maintained against the leg, and the muscle becomes fatigued. Swelling of the joint is demonstrated by placing the thumb over the femoral artery where it crosses the inguinal ligament and the other four fingers posteriorly over the buttock opposite the position of the thumb. In this way the joint with the soft tissues anterior and posterior to it is grasped between the thumb and the fingers. When the hip joint is swollen with fluid, the involved hip will feel thicker than the opposite one (Gill's sign).

It is impossible to distinguish the joint lesion of trauma from that of early Perthes' disease before roentgen changes have become manifest. If the roentgen examination is negative, the child should be put to bed for three or four days. If the spasm persists, the child should have Buck's traction on both legs for three weeks. If the signs of spasm have then disappeared, as they usually will have if trauma has been the cause, he is allowed gradually increasing activity. If spasm persists, traction is continued for another three weeks, when the roentgen examination is repeated. The characteristic changes of Perthes' disease will usually have appeared by then.

*Perthes' disease* (Legg-Calvé-Perthes disease) is an aseptic necrosis of the capital femoral epiphysis causing signs and symptoms of synovitis as described above followed by characteristic roentgen changes. Three stages are usually described, each lasting about nine months to one year. The first stage is one of aseptic necrosis; roentgenographically there may be no change during the first weeks, after which a relative opacity of the epiphysis becomes evident. The second stage consists in revascularization, and the epiphysis becomes mottled and fragmented. In the third stage there is reossification, and the roentgenogram appears much as it did in the second stage, but serial films demonstrate gradual re-formation of the head of the femur. The principle of treatment is avoidance of weight bearing by any of several methods. The head of the femur tends to flatten and become mushroom-shaped, causing incongruity between head and acetabulum with degenerative changes later in life. The main prognostic factor as far as the eventual shape of the head of the

femur is concerned is the age of the child at time of onset: the younger the child, the better the chance for a spherical rather than a flat head.

*Slipped epiphysis* occurs typically in the adolescent and also is responsible in its early stages for the signs and symptoms of synovitis. The cause is unknown, but the condition occurs mostly in the "overlarge" child. The onset is insidious and characterized by pain in the knee, so that hip disease may not be suspected even though the child limps. Roentgen examination will reveal that the femoral capital epiphysis has slipped posteriorly and inferiorly. This is shown invariably on the lateral projection, but not always on the anterior-posterior one, so that the diagnosis may be missed if a lateral view is not obtained. The anterior bowing of the neck which occurs as the "slip" progresses makes subsequent therapy difficult, so that early diagnosis is of real importance.

The principle of treatment is arrest of the slipping, which is usually attained by internal fixation, followed by avoidance of weight bearing (crutches) until healing has occurred.

## THE SPINE

### SPONDYLOLISTHESIS

In this condition there is an anterior displacement of a lumbar vertebra, usually the fifth, associated with a bilateral defect in its isthmuses. The cause is unknown. In children under ten years of age spondylolisthesis usually does not cause symptoms and is an incidental finding on a roentgenogram. If the vertebral body continues to be displaced forward as shown by serial roentgenograms, spinal fusion is indicated. Symptoms may appear in the adolescent child. Pain in the low-back area is occasionally referred to the sciatic area, and there is an increasing lumbar lordosis. When such symptoms are present, a brace should be provided, and spinal fusion is indicated if the symptoms persist or if the slipping progresses.

### SCOLIOSIS

Scoliosis is an S-shaped lateral curvature of the spine (Fig. 385). If the scoliosis is correctible by bending toward the side of the curvature, the most common cause is a short leg on the affected side. Such a correctible scoliosis may also be the result of poor posture.

A fixed scoliosis, which is not correctible by bending, is most frequently idiopathic, but may be caused by such lesions as hemi-

FIG. 385. Scoliosis in a girl 10 years of age, showing the tilt of the pelvis and shoulders and the deformity of the chest.

vertebrae, fusion of ribs, absence of muscles, neurofibromatosis of the vertebrae, vertebral infections such as tuberculosis and poliomyelitis.

Treatment consists in bracing to prevent increase of the curvature, and spinal fusion after growth has been completed.

### OSTEOCHONDROSIS

(OSTEOCHONDROITIS DEFORMANS JUVENILIS, AVASCULAR NECROSIS)

Osteochondrosis is characterized by the fragmentation of epiphysial centers. Its cause is unknown, but osteochondrosis of the hip has been observed in children after reduction of a dislocation and after long immobilization in a cast. Although almost any epiphysis may be involved, there is a definite predilection for certain ones, and, in the individual child, involvement is usually limited to a single epiphysis. The lesion is known by various names, depending on the affected epiphysis. Among these are Freiberg's disease of a metatarsal head, Koehler's disease of the tarsal navicular, Osgood-Schlatter's disease of the tibial tubercle (Fig. 386), Legg-Calvé-Perthes disease (p. 1257) of the femoral

FIG. 386.

FIG. 387.

FIG. 386. Osteochondrosis of tibial tubercle (Osgood-Schlatter's disease) in a boy 13 years of age. Roentgenogram shows irregular ossification of tibial tubercle and associated thickening of infrapatellar tendon.

FIG. 387. Legg-Calvé-Perthes disease of the left hip in a boy 6 years of age. The presenting complaints were limp and pain in the left knee. The lateral roentgenogram reveals sclerosis of the femoral capital epiphysial center, which is also fragmented and flattened. The "joint space" is wider than normal. At this stage there is little deformity of the neck of the femur.

capitular epiphysis (Fig. 387) and Scheuermann's disease of the vertebral epiphyses.

The outstanding symptom is pain in the affected part with voluntary restriction of motion. When the involved epiphysis is in the foot, leg or hip, there is a protective limp.

Roentgenograms show epiphysal irregularities in which there appears to be an area of poorly calcified and rapidly growing bone surrounded by a densely calcified ring. Later there may be fragmentation of the center ending in malformation if weight bearing is continued (Figs. 386, 387).

**Prognosis and Treatment.** The disease is self-limited and, despite bony distortion, usually terminates with restoration of satisfactory function, provided weight bearing is avoided during the active stage.

## SUBLUXATION OF HEAD OF RADIUS

Subluxation of the head of the radius occurs frequently in young children two to five years of age; it is rare after nine years of age. The child has usually been forcibly jerked by the hand by a taller person while the elbow is in full extension; the subluxation occurs with an audible snap.

The *symptoms* are immediate but usually not persistent pain in the elbow, an inability to supinate the hand and a tendency to hold the arm in slight flexion. Palpation and roentgenograms of the elbow do not reveal any abnormality, and there is no edema. The *diagnosis* is confirmed by the easy therapeutic maneuver of reduction of the subluxation. This is accomplished by firmly grasping the hand of the affected arm and holding the elbow with the thumb of the other hand pressed against the head of the radius while forcibly supinating the forearm beyond the point of obstruction. The click of the return of the radial head to position is usually followed by immediate recovery of painless function.

## INFECTIONS OF THE BONES AND JOINTS

### ACUTE INFECTIOUS ARTHRITIS

This condition is most common in the first six months of life. It is usually preceded by an infection elsewhere in the body, often in the upper respiratory tract. The causative organism is usually one of the common pyogens, such as the *Staphylococcus*, *Streptococcus*, *Pneumococcus* and, less commonly, the *Gonococcus*, *Meningococcus*, influenza bacillus, typhoid bacillus or one of the *Salmo-*

nella group of organisms. The shoulder, hip and other large joints are most commonly affected, but any joint may be involved.

**Clinical Manifestations.** The onset is sudden with systemic symptoms of sepsis. Local swelling appears rapidly with pain and muscular rigidity and, if untreated, is followed promptly by suppuration. When the hip is affected, it may become dislocated with astonishing rapidity, even in the absence of demonstrable suppuration.

**Differential Diagnosis.** Acute suppurative arthritis must be differentiated from *acute osteomyelitis*. In acute suppurative arthritis even slight motion of the joint is painful, whereas in osteomyelitis the joint may be moved without pain if done carefully. The tenderness is localized to the metaphysal region of the bone. In the hip the differentiation cannot be made. The roentgenogram is of no value in early diagnosis. *Rheumatic fever* is excluded in infancy since it rarely occurs at this age.

**Treatment.** When an acute pyogenic infection of a joint is suspected, it should be aspirated, and any material obtained cultured. A blood culture should also be obtained, and broad-spectrum antibiotic therapy started immediately. Subsequently any indicated adjustment should be made on the basis of bacterial susceptibility tests in vitro and the clinical response. If there is no evidence of improvement within twenty-four hours, the joint should be drained surgically.

## OSTEOMYELITIS

This disease occurs most often between five and fourteen years of age and twice as frequently in boys as in girls. In infants under two years of age acute hematogenous osteomyelitis differs in many respects from that in older children.

**Etiology and Predisposing Factors.** The causative organism in the majority of cases in older children is the hemolytic *Staphylococcus aureus*. Predisposing causes are often demonstrable and include furunculosis, impetigo, chickenpox and infected burns and vaccinations.

**Pathology.** Osteomyelitis begins as a hematogenous abscess in the metaphysis, and then, if uninterrupted, the abscess ruptures subperiosteally and spreads along the shaft of the bone. The infection then penetrates to the bone marrow. The separated periosteum forms a shell of new bone around the infected shaft. The pieces of dead bone are known as sequestra, and the new bone formed by the

periosteum as the involucrum. Sinuses may form between the sequestra and the skin surface. In the hip the metaphysial abscess ruptures into the joint and becomes a suppurative arthritis.

**Clinical Manifestations.** The onset is usually abrupt with fever, malaise, and pain with sharply localized tenderness in the affected bone. Shortly thereafter, swelling and redness over the affected bone may be present. These signs appear earlier in infants than in older children. The patient is toxic and extremely weak and irritable.

When osteomyelitis follows an infection which has been treated with an antibacterial agent, the clinical course may be modified sufficiently so that the true nature of the lesion may not be suspected until it is well advanced. In addition, inadequate antibacterial therapy of an acute osteomyelitis infection may temporarily abolish the clinical manifestations, but permit the infection to continue in a temporarily suppressed state only to become evident some days or weeks later.

**Diagnosis.** There is a leukocytosis of 15,000 to 25,000 or more, and the blood culture is usually positive. Roentgenographic examination does not reveal the process for at least five days in small children; in older children this period may be as long as eight to ten days. Initially there is rarefaction of the involved area, and soon there is evidence of the formation of involucrum.

**Differential Diagnosis.** Rheumatic fever, sprain, cellulitis, erysipelas and scurvy, in particular, are likely to require differentiation. The presence of great toxicity and localized pain suggests osteomyelitis. Usually this is enough to distinguish the condition from *rheumatic fever*, but a history of involvement of other joints is indicative of the latter disease, as is the response to salicylates. *Scurvy* produces painful and tender swelling along the shaft of the bone, but roentgenograms of the long bones should be diagnostic. See also Acute Infectious Arthritis.

**Prognosis.** The mortality rate from acute pyogenic infections of the bones has decreased markedly since the availability of specific antibacterial agents. The rate is lower in newborn infants than in older infants and children, as is the incidence of chronic and metastatic lesions. Both the course and prognosis depend on early institution of appropriate therapy and continuance of it for an adequate time.

**Treatment.** Acute osteomyelitis requires immediate treatment. When an acute pyogenic infection of a joint or bone is suspected, a blood culture should be obtained, and antibacterial therapy should be started immediately. In view of the frequency with which pathogenic strains of staphylococci are resistant to the available antibiotics, two of those known to be effective against many of the strains should be selected for initial therapy and continued except as the cultural tests in vitro or the clinical course show one or both of them to be ineffective. Whenever antibiotic therapy is instituted for a *possible* osteomyelitis and is apparently clinically effective, it should be considered obligatory to continue it in full dosage for at least two weeks after the temperature has been normal. Less prolonged therapy may only temporarily suppress the lesion and permit it to become reactivated. Surgical intervention may not be needed, but the extremity should be immobilized, and if an abscess forms, it should be drained immediately. If the child is seen while the lesion is still confined to the metaphysis, some clinicians believe that this area should be drilled and drained in the hope of avoiding further extension.

#### INFANTILE CORTICAL HYPEROSTOSIS

This lesion, also known as Caffey's disease, is a hyperplasia of subperiosteal bone (Fig. 388) over which there is soft tissue swelling and at times a brawny discoloration of the skin. Hyperostoses have been observed in the calvarium, mandible, clavicles, scapulas, ribs and the long bones of the extremities, including the metatarsals. The mandible and clavicles appear to be most frequently affected. The clinical features vary considerably, but the symptoms are not severe as a rule. Fever, usually of a low degree, tenderness, hyperirritability, pseudoparalysis, dysphagia, pleurisy, anemia, increased sedimentation rate and elevated serum phosphatase have been observed in variable combinations.

Duration of clinical activity has been observed for as long as nine months. No treatment has been effective. Recovery has occurred in all reported instances, and there are no recorded residuals.

*Hypervitaminosis A* (p. 363) may simulate infantile cortical hyperostosis in certain respects. In hypervitaminosis A the ulnas and one or more metatarsals, other than the first, have been the bones most frequently involved; the mandibles and other flat bones

FIG. 388. Infantile cortical hyperostosis. A (3/20/43), Subperiosteal calcification of left lower ribs and left humerus. No evidence of bone destruction. The infant was moderately ill with an upper respiratory tract infection and was somewhat listless. The only localized finding was a disinclination to use the left arm, but there was no paralysis of it. B (4/19/43). Increase in subperiosteal calcification of ribs of left side and left humerus within 1 month. There is similar involvement of lower right ribs and of facial bones. Evidences of illness had mostly disappeared at the time this roentgenogram was made. C, One and a half years later there is no evidence of the cortical disturbance.

are apparently not affected. This distribution plus a history of excessive ingestion of vitamin A serves to distinguish this entity.

## TUBERCULOSIS

### TUBERCULOUS LESIONS OF THE BONES AND JOINTS

These lesions are hematogenous in origin, usually stemming from a pulmonary focus, which may not be demonstrable. There is usually only a single lesion. The bones most frequently involved are the head of the femur (hip), the vertebrae, the fingers and toes.

### TUBERCULOUS DACTYLITIS

Dactylitis occurs most frequently in early childhood and involves one or more of the phalanges, the metacarpal bones or the corre-

sponding bones of the feet. The medullary canal of the involved bone becomes caseous; the cortex, thinned and expanded; the periosteum, thickened. The entire digit develops a spindle-shaped, hard and red swelling as

FIG. 389. Tuberculous dactylitis in an infant 11 months of age.

the soft tissues are affected (Fig. 389). The process is comparatively painless, but it lasts many months and may leave a permanent deformity. The *differential diagnosis* is chiefly from the dactylitis of congenital syphilis, which is more often multiple and symmetric. Dactylitis may also occur in sickle cell anemia and in coccidioidomycosis.

*Treatment* consists in measures for tuberculosis in general. The involved region should be put at rest with a splint or cast, and operation is indicated if an abscess develops. Antibacterial therapy is discussed on page 464.

### TUBERCULOUS SPONDYLITIS

#### (POTT'S DISEASE)

This tuberculous osteitis originates in the body of one or more vertebrae, destroys the bone and spreads to all the tissues of the articulation. The spinous process and arches are unaffected. Kyphosis is most common in mid-dorsal lesions. Some scoliosis may accompany the kyphosis if the lesion is disproportionately unilateral.

The lower dorsal part of the spine is most likely to be involved, with the lumbar and the cervical segments next in order of frequency. Paraplegia occurs in about half of the cases of caries of the upper dorsal or cervical region, but is rarely associated with involvement below the mid-dorsal region. The average duration of tuberculous spondylitis before paralysis appears is about three years, but paralysis may develop even within a few months. Psoas abscess is a complication of caries in the lumbar vertebrae. A cold abscess in the cervical vertebrae may open into the pharynx (retropharyngeal abscess) or above the clavicle; one originating opposite the lower cervical or upper dorsal vertebrae may rupture into the pleura or penetrate to the scapula, but often it gravitates, like abscesses originating in the lower dorsal and lumbar regions, and points above Poupart's ligament.

**Clinical Manifestations.** Symptoms are insidious in onset, the earliest being fretfulness and disturbed sleep. Persistent or intermittent pain may occur over the distribution of the spinal nerves arising adjacent to the affected vertebrae. This pain is increased by pressure on the head, but not by pressure over the lesions. Muscular rigidity splints the back, and the child assumes a position which will best take the weight from the diseased spine and prevent jarring. He may avoid bending to reach an object on the floor, may walk stiffly or carefully on his toes, or may prefer to lie

on his abdomen and to rest frequently across a chair or over his mother's lap. With cervical involvement the child may hold his head stiffly or support it with his hand.

**Differential Diagnosis.** Rickets produces kyphosis of greater length and uniformity, which is unaccompanied by rigidity and disappears when the patient is prone. *Nontuberculous scoliosis* is seldom accompanied by rigidity or pain. *Hip joint disease* may be suspected when lameness is the result of lumbar caries, but in the latter there is no limitation of movement of the hip except in the presence of psoas abscess, when extension will be limited. *Acute nontuberculous osteomyelitis of the vertebrae* can be distinguished by its greater toxicity, leukocytosis and fever. In addition, the roentgenographic findings are usually well established in a tuberculous lesion of the vertebrae when symptoms first become manifest, whereas they are not likely to be demonstrable during the first few days of an acute pyogenic osteomyelitis. The *Klippel-Feil syndrome* may be confused with tuberculosis of the cervical spine, but is readily distinguishable by roentgenogram.

**Prognosis.** The reparative process may not begin for one to three years, but in carefully treated cases recovery with ankylosis and little or no deformity can be expected. Paraplegia often disappears completely. There is danger of relapse from trauma or other causes. Though a large number of children eventually recover with varying degrees of deformity, the prognosis is serious.

**Treatment.** Traditionally, therapy consists in continuous extension on a Bradford frame until evidences of infection are no longer present, and then spinal fusion. Some experience with early surgical eradication of the tuberculous abscess in conjunction with specific antimicrobial therapy has been encouraging.

### TUBERCULOSIS OF THE HIP

#### (TUBERCULOUS COXITIS)

This is the most common tuberculous involvement of the joints. The disease may begin in the synovial membrane, but usually starts as an osteitis of the femoral epiphysis, followed later by a tuberculous arthritis and finally by an abscess resulting in destruction of the femoral head, with displacement and deformity. Recovery may begin at any time.

**Clinical Manifestations.** Usually the first symptom is a slight lameness which is likely to be intermittent, occurring when the pa-

tient first gets out of bed and after exercise. It may disappear for days or weeks at a time. Pain may be present at this stage or may develop later and is usually referred to the knee or the inner side of the thigh. As destruction of the joint proceeds, the thigh is flexed and adducted, and the rotation which initially was outward becomes inward. Swelling about the hip increases, and an abscess may form from which pus may discharge anteriorly to the joint or burrow in other directions. Absorption of the head and neck of the femur may take place without visible evidence of suppuration.

**Differential Diagnosis.** Distinction must be made from *osteochondrosis of the femoral head* (Legg-Calvé-Perthes disease) which occurs in the same age group, but limits abduction to a greater extent than it does extension and whose roentgenographic changes do not extend beyond the femoral capitular epiphysis. In tuberculous coxitis the acetabulum may also be affected. Frequently the two

conditions may be indistinguishable on early films, and the clinical course must be relied upon to differentiate them. A negative tuberculin reaction is of great value. The insidious onset of tuberculous coxitis serves to distinguish it from *rheumatic fever* and *acute arthritis*. *Chronic arthritis* usually begins in the fingers and involves the hips only late in the disease.

**Prognosis.** After abscess formation the disease may last two to four years or longer. When treatment is begun in the first few weeks of the disease, the inflammation may cease entirely before the joint itself is attacked, but in the majority of cases the joint is finally ankylosed. After apparent recovery, recurrences may take place from slight trauma or overuse of the limb.

**Treatment.** See treatment of tuberculosis of the hip.

CHARLES C. CHAPPLE  
JOHN ROYAL MOORE

# The Muscles

Various diseases may be accompanied by secondary changes in striated muscle and must be differentiated from primary diseases of muscle. Muscular atrophy may accompany states of malnutrition, rickets, hyperthyroidism, malignancy or chronic debilitating diseases of many types. Hypertrophy of muscles may occur in hypothyroidism, in diseases of the adrenal and pineal glands or with devel-

opmental defects of the brain in the region of the corpus striatum. Myasthenia and periodic paralysis have been described in hyperthyroidism. These secondary manifestations in muscle may be differentiated from primary diseases of muscle by consideration of pertinent facts in the history and physical examination as well as by the response to therapeutic agents.

## CONGENITAL DEFECTS OF MUSCLE

Developmental abnormalities in the fetus may lead to defects or absence of various skeletal muscles. Apparently any of the skeletal muscles may be congenitally absent in whole or in part, but certain muscle groups are more likely than others to be affected. The muscles most frequently involved are the pectoralis major, pectoralis minor, trapezius, quadriceps femoris, serratus magnus, semimembranosus, abdominalis, gemelli, deltoid, latissimus dorsi and levator palpebrae. Usually the defect is unilateral and involves only a single muscle group. Frequently the absence of a muscle group occurs in association with congenital abnormalities of other organs.

Developmental anomalies producing shortening of various muscles may cause contractural defects. Congenital torticollis results when neck muscles are thus involved. If muscles of the calf are affected, contractural defects of the feet and clubfoot are found. Elevation of the shoulder (Sprengel's deformity) may be caused by anomalous development of either the trapezius or serratus magnus muscles. *Amyoplasia congenita* or *arthrogryposis multiplex congenita* is a syndrome accompanied by immobility of one or more joints of the extremities associated with developmental defects of muscles about these joints. The affected joints are usually fixed in positions of extension.

### TORTICOLLIS

(WRYNECK)

Torticollis is accompanied by shortening or spasm of the cervical muscles and malposition of the head and neck. When the defect is evident at birth or within the first few weeks of life, it is designated as congenital torticollis. If the onset is at a later age, the condition is regarded as acquired.

### CONGENITAL TORTICOLLIS

Congenital fusion of the atlas and occipital bone or of the atlas and the axis, malformations of cervical vertebrae and cervical ribs may be responsible for the production of this defect. If a bony abnormality is not demonstrable, the defect may be considered to be of muscular origin. Congenital muscular torticollis usually results from trauma of a difficult delivery or from an abnormality in fetal position. In some instances a firm fusiform mass may be palpated in the body of the sternocleidomastoid muscle at birth or shortly thereafter. The size of the tumor may increase slowly for several weeks and then decrease, so that the mass may no longer be palpable by the sixth to eighth month. Recovery may occur without residual deformity. In other instances the muscle becomes small, short, fibrous and noncontractile.

FIG. 390. Acquired torticollis, demonstrating tilting of the head and facial asymmetry. (Courtesy of Dr. Herbert R. Kobes.)

Some observers believe that congenital muscular torticollis results from a hematoma in the damaged muscle, with later replacement by a fibrous mass; others, that the lesion has a fibrous structure from the onset.

**Clinical Manifestations.** Manifestations are dependent on the muscle groups affected and the causative factors involved. Character-

istically, the head is drawn downward, the neck shortened on the side of the lesion, and the chin tilted (Fig. 390). Facial asymmetry develops. If the trapezius muscle is involved, the head is drawn backward. A tumor mass may often be palpated in the sternocleidomastoid muscle. Roentgenographic search for skeletal anomalies of the cervical area should also be made.

**Treatment.** The management of congenital torticollis is described on page 320.

#### ACQUIRED TORTICOLLIS

Inflammation of the cervical muscles secondary to cervical adenitis, mastoiditis or arthritis may produce torticollis. Manifestations have followed exposure to cold or efforts to make postural adaptations in compensation for defects of vision or hearing. Rarely torticollis is a manifestation of hysteria.

**Clinical Manifestations.** The symptoms and signs are those of congenital torticollis.

**Treatment.** Treatment for acquired torticollis must be adapted to the cause. Acute inflammatory myositis is best treated with rest, heat and salicylates and with appropriate treatment of any infection in other sites. Treatment of visual and auditory defects is indicated when torticollis represents a postural adaptation to either of such defects. Habit spasm and hysteria require correction of the underlying emotional factors responsible for them.

## INFLAMMATORY DISEASES OF MUSCLE

Skeletal muscle may be the site of local inflammation. Bacterial infection is rare except in association with traumatic lesions or infection in adjacent structures. The *Streptococcus* and *Staphylococcus* are the most common causative organisms of suppurative myositis, but other organisms, including that of clostridial infection producing gas gangrene, may affect the muscles of children. Rarely myositis occurs by direct spread from a localized tuberculous process in adjoining tissues, and tuberculous myositis produced by hematogenous dissemination has been described. Trichinosis is discussed on page 587. Inflammatory changes may occur in association with various infectious diseases, including those of the upper respiratory tract.

#### DERMATOMYOSITIS

See page 922.

#### MYOSITIS FIBROSA

##### (CHRONIC POLYMYOSITIS)

This rare syndrome is a poorly defined subacute or chronic disease of muscle characterized by loss of muscular power and by atrophy and contractures. The etiology is unknown. The pathologic changes are those of muscular degeneration with gradual replacement of muscle by fibrous connective tissue.

**Clinical Manifestations.** The onset is insidious, and constitutional symptoms are lacking. Any or all of the skeletal muscles may be

involved. Frequently the muscles of the thighs and calves are first affected with extension of the process to those of the hips, abdomen, spine, thorax and neck. The muscles are shortened and inelastic, but not painful. As the disease progresses they become firm and woody in consistency. Contractures develop, which are usually of the flexion variety and result in deformities.

**Diagnosis.** The disease is differentiated from *dermatomyositis* by the absence of skin lesions and lack of constitutional symptoms. It is not always readily possible to distinguish this disorder from progressive muscular dystrophy. A diagnosis of *myositis fibrosa* is sometimes applied to localized lesions which tend to regress, but it would seem preferable to include the localized and more or less self-limited processes under such diagnoses as *fibrositis* or *intramuscular fibrositis*.

**Treatment.** Treatment is limited to measures designed to alleviate and correct resultant contractures. The outcome may be fatal, but in some instances remissions occur or the disease becomes arrested.

### PROGRESSIVE MYOSITIS OSSIFICANS

This disease is rare and results in deposition of masses of bone or areas of calcification in muscles, tendons, ligaments and fascial sheaths. It is usually first observed in children and progresses through phases of exacerbation and regression until complete invalidism occurs. Males are more often affected than females. Various congenital anomalies are observed in about 75 per cent of patients afflicted with the disease, microdactylia of the great toes or thumbs being the most frequent one.

**Etiology.** No causative factor is known. Infections and trauma often precede the onset or exacerbations of the disease. There are some indications that the disorder may be associated with a congenital metabolic aberration of osteoblastic tissue.

**Pathology.** Discrete masses of bone are formed in the skeletal muscles. Late in the disease it is sometimes possible to demonstrate a nearly continuous band of bone from the occiput to the pelvis. The joint capsules may be affected, resulting in complete ankylosis. Microscopic changes include replacement of

the connective tissue network of the skeletal muscle by an embryonic type of connective tissue which later forms firm, thick fibrous bands containing cartilage cells and osteoid trabeculae. Calcified intramuscular lesions are structurally and chemically indistinguishable from bone. Muscle fibers caught within the fibrous and calcified network atrophy and undergo degeneration.

**Clinical Manifestations.** The onset may be noted after an acute infection or injury, or without any preceding incident, and is characterized by low grade fever, pain and the appearance of small soft tumors in the involved musculature. The muscles first affected are usually those of the neck and back. There is gradual spread to other muscles, and in advanced cases most of the skeletal muscles may be involved. Those of the hands, feet, tongue, heart, diaphragm, larynx and sphincters escape, as do smooth muscles. The soft muscular tumors may break down and extrude a white or gray material. Erythema of the overlying skin occurs before this extrusion. After a relatively short interval the muscular swelling recedes and is replaced by areas which are firm to palpation, the firmness and density of these lesions increasing as ossification proceeds.

Low grade anemia may accompany the disease. No abnormalities in the chemical constituents of the blood have been demonstrated, but phosphatase activity of the muscles prior to ossification may be increased. Roentgenograms demonstrate calcium deposits with true bone formation.

The disease must be distinguished from *myositis ossificans circumscripta*, in which localized calcium deposits occur in muscles as a result of trauma. It must also be differentiated from multiple exostoses, *myositis fibrosa* and *dermatomyositis*.

**Prognosis and Treatment.** There may be prolonged remissions of the disease, but exacerbations follow and death eventually occurs. When the onset is in infancy or early childhood, patients seldom live longer than the age of puberty. Many types of therapy have been attempted, but all have been without effect, except that remissions have been reported with corticosteroid therapy in the early stage of the lesions.

# METABOLIC AND DEGENERATIVE DISEASES OF MUSCLE

## AMYOTONIA CONGENITA SYNDROME

(OPPENHEIM'S DISEASE)

There is much confusion concerning the various conditions responsible for hypotonia in infants and children. Part of this confusion is related to the varied terminology, but lack of adequate knowledge is the larger factor. The term "Werdnig-Hoffman disease" is now rather widely used for the preferable one of progressive muscular atrophy of spinal origin, a genetic disturbance which is entitled to designation as a clinical entity. There does not seem to be any reason to continue the use of the term "Oppenheim's disease." The conditions responsible for generalized hypotonia in infancy are discussed on pages 1095 and 1099 as the amyotonia congenita syndrome.

## MYOTONIA CONGENITA

(THOMSEN'S DISEASE)

Myotonia congenita is a hereditary muscular affection in which muscles stimulated by voluntary, mechanical or electrical means remain in the contracted state for an abnormally long time. The disease was first described in 1876 by Thomsen, whose observations were derived from members of his own family, in which the disease had existed for seven generations.

**Etiology.** The primary defect in this disorder has not been clearly elucidated. Myotonia occurs with mechanical and electrical stimulation applied to the muscle after blocking the motor nerve. One concept is based on a primary defect resulting in hyperexcitability of muscle fibers so that a single excitation leads to a repetitive series of discharges with progressively diminishing action potential rather than a single muscular twitch. The fact that drugs with cholinergic effects, such as neostigmine, enhance the degree and period of myotonia lends support to this concept. Denny-Brown and Foley, however, do not believe that neuromuscular transmission is disordered, but that the responsible mechanisms is an accumulation of a by-product of contraction, a chemical mediator of intracellular origin.

The physiologic defect is accompanied by

few morphologic changes. However, all fibers of involved muscles are hypertrophic. There are no evidences of degeneration.

**Clinical Manifestations.** The onset is usually noted in early childhood, but manifestations of the disease may not be observed until young adulthood. The characteristic sign is occurrence of sustained contraction of muscles when the patient attempts to use them after a period of rest. Voluntary relaxation may be delayed for five to thirty seconds after contraction. Movements become easier with repetition, and contractions less prolonged. The muscles of the legs are most frequently involved. The patient starts to walk haltingly and slowly, but after a few steps the imperfection of gait disappears, and walking becomes normal. After grasping an object the sustained contraction of muscles of the hand and forearm may make it impossible to release it for several seconds. Most of the striated muscle may be involved. The affection may be severe in some muscle groups and slight in others, and involvement may be greater on one side than on the other. The condition is aggravated by cold, rest, apprehension, fear, excitement, febrile illnesses and forced effort. Seldom are the muscles of respiration or of the pharynx affected.

The muscles of patients with myotonia congenita are usually well developed or even enlarged. Atrophy and contractures do not occur. In the presence of muscular atrophy associated with myotonia, a diagnosis of myotonic dystrophy is indicated.

After mechanical stimulation of the muscles of patients with myotonia, contraction of the fasciculi persists for many seconds with a concavity at the site of mechanical impact. Electrical stimulation, either faradic or galvanic, of moderate intensity produces the "myotonic reaction," in which contraction persists as long as current is applied, and then relaxes slowly.

**Prognosis.** The condition may persist relatively unchanged throughout life, the only hazard being that of accidents contributed to by the myotonia.

**Treatment.** Quinine is effective in reducing the myotonia. For adults a dose of 0.3 to 0.6 gm. (5 to 10 grains) of quinine hydrochloride or sulfate two or three times daily

is usually adequate. Proportionately smaller doses should be administered to children. Patients may learn to adapt to their handicap by engaging in a brief period of "warming up" before undertaking certain movements.

### MYOTONIC DYSTROPHY

This is a rare familial disease accompanied by muscular atrophy and the phenomenon of myotonia. Frequently associated with it are alopecia, cataract, and atrophy of the sex glands. Males are affected about five times as frequently as females. The onset is usually in young adult life, although symptoms may appear in childhood.

**Etiology and Pathology.** Myotonic dystrophy is transmitted as either a dominant or a simple recessive factor. It may appear in one or several generations of a family, and there may have been cataracts and other congenital defects in previous generations. Gonadal atrophy accompanying the disease prevents propagation of the disease through affected persons.

Pathologic manifestations in muscle differ with the degree of atrophy. Early in the disease, muscle fibers vary in size and are rounded in cross sections. In swollen fibers rows of nuclei may accumulate beneath the sarcolemma or in the center of the fiber. With more extensive atrophy there are evidences of widespread degeneration and replacement of muscle by fat and connective tissue. Lesions do not occur with constancy in the nervous system, and those observed are usually considered secondary to primary involvement of the muscle. Morphologic changes have been infrequently observed in the pituitary, adrenal and thyroid glands. The testes may be atrophic.

**Clinical Manifestations.** Muscular weakness and atrophy develop initially in the muscles of mastication and of the face and neck. Delayed relaxation following initial contraction of muscles may appear before, concurrently or after the development of atrophy. This myotonia is analogous to that of myotonia congenita, except that atrophy does not accompany the latter disorder. The myotonia of myotonic dystrophy is frequently limited to muscles of the forearms and legs. Other abnormalities such as baldness, cataracts or testicular atrophy may also be present, and mental deficiency is common.

**Prognosis.** The disease is slowly progressive; contractures develop and disability in-

creases. Death usually occurs before the age of forty-five years, pneumonia being the most common cause.

**Treatment.** Myotonia sometimes is controlled by administration of quinine, but such therapy in no way affects the progress of muscular atrophy. Other therapy includes procedures which will moderate the discomforts attendant upon the deformities.

### PROGRESSIVE MUSCULAR DYSTROPHY

This is one of the more common primary diseases of muscle. It is characterized by weakness and atrophy of the skeletal muscles with increasing disability and deformity as the disease progresses. Several clinical types are recognized, but muscular atrophy occurs in all forms; pseudohypertrophy appears as an early and prominent sign in one form. Genetic patterns are varied and may be of a sex-linked, simple recessive or dominant type. Muscular dystrophy accompanied by pseudohypertrophy is usually transmitted by a sex-linked factor, and most cases of facioscapulo-humeral dystrophy appear through a dominant genetic pattern. Manifestations of the disease are likely to occur early in life when it has been transmitted through sex-linked or simple recessive factors. In contrast, when a dominant mode of inheritance is involved, the onset occurs later in life. The disease occurs about three times as often in males as in females. Moreover, muscular dystrophy occurring in females is likely to be less severe and less rapidly progressive.

**Pathology.** There are no essential differences in the pathology of the various clinical types of the disease. On gross examination the muscles are pale and fibrous. In pseudohypertrophic muscles, fatty infiltration is responsible for producing a characteristic yellow color on gross section. True muscular hypertrophy is seldom if ever observed at necropsy. Microscopically, there are evidences of cellular degeneration. Muscle fibers vary in diameter, some appearing small and shrunken, others large and swollen. Accumulations of nuclei are found along the sarcolemmal sheath. There is fragmentation of fibrils and evidence of hyaline and granular degeneration. On cross section, muscle fibers will be seen to have lost their polygonal shape and are rounded or oval, individual fibers being widely separated from each other by fat, fibrous connective tissue and areolar tissue. Late in the disease connective tissue

replaces most of the muscle mass, and only occasional, small, degenerative muscle fibers will be observed.

The myocardium may show similar changes, but usually the process affecting the cardiac muscle is less marked. Smooth muscle is unaffected. Changes in the anterior horn cells have been described, but these are irregular in occurrence and cannot be considered responsible for the profound muscular atrophy. Decalcification and osseous atrophy are found in late stages. Thick, soft accumulations of subcutaneous fat often appear about the pelvic girdle and shoulders.

The disease is accompanied by creatinuria in adults and excessive urinary excretion of creatine in children. Creatinine excretion, however, is decreased. There is, in addition, increased urinary excretion of glycoxyamine, an intermediary compound in the biologic synthesis of creatine. When the precursors of creatine, the amino acids glycine, arginine and methionine, are provided in adequate amounts, glycoxyamine and creatine are excreted in the urine, indicating that there is no defect in the synthesis of these materials. Urinary excretion of creatinine correlates in some measure with the amount of residual functional muscle. As the disease progresses, creatinine excretion decreases.

**Clinical Forms.** All clinical forms of muscular dystrophy may be considered variations in manifestations of a single disease, differing only in the muscle groups affected, the age at onset and rate of progression. A single case may have characteristics of several forms. In deference to classic nomenclature, and since clinical manifestations greatly depend on the particular groups of muscles affected, the more important clinical forms of muscular dystrophy are described.

**Pseudohypertrophic form.** This is the most common form in childhood. The onset is usually before the fifth year of life. Certain muscle groups are enlarged, representing characteristic pseudohypertrophy. Atrophic changes are noted in other muscles and follow in muscles initially enlarged. Sex-linked or simple recessive genetic factors are effective in its transmission. The disease is progressive, few patients living past the age of puberty.

The first signs are noted in rare instances in infancy or early childhood, the child finding it difficult to stand or learn to walk. More often the child is observed to have gradually increasing weakness of the lower extremities. A waddling gait results from weakness of the gluteal muscles, and he walks with his feet

thrown widely apart. He may fall frequently. Riding a tricycle or ascending stairs may become impossible. The child may be unable to comb his hair or raise his hands above his head because of involvement of the muscles of the shoulder girdle. Weakness of the shoulder muscles is manifested by the manner in which the arms slip upwards and through the examiner's hands when they are placed in the axillas in an attempt to lift the child.

A characteristic feature is the patient's inability to arise readily to an upright position from a sitting position on the floor (Fig. 391). The patient turns on his side, flexes his knees and hips, and with arms extended raises his trunk to assume a position of kneeling. The feet are brought forward and the legs extended at the knees. Then by bringing the hands successively to the shins, knees and thighs, he pushes his body to the upright position. This succession of movements is generally considered pathognomonic of progressive muscular dystrophy.

In the upright position there is marked lordosis, and the abdomen is thrust forward prominently. The pelvis and sacrum tilt anteriorly, and there is forward inclination of the lumbar vertebrae. Winging of the scapulas may be noted.

Muscles are usually involved symmetrically. Pseudohypertrophy is observed most frequently in the infraspinatus, supraspinatus, deltoids and triceps, and in the muscles of the calves. Macroglossia sometimes occurs. Usually the muscles of the face and of the forearms are unaffected. Atrophy is usually first observed in the sternal portion of the pectoralis major. As the disease progresses there is also atrophy of the deltoid, triceps, biceps, gluteus and the anterior thigh muscles. Atrophy begins near tendinous ends, so that on contraction the muscle stands out in bold relief. Late in the disease all muscles of the lower extremities, spine, pelvis and shoulder girdle are atrophic. In some instances there are large subcutaneous depositions of fat, which tend to preserve body contours; in others the extreme muscular atrophy results in an appearance of inanition. Contractures and skeletal deformities result.

Tendon reflexes may be normally active early in the disease, but become hypoactive and later disappear as the muscles become too weak to respond to stimuli. Superficial reflexes are unchanged. Fasciculation does not occur. Response to electrical stimulation is decreased, but the reaction of degeneration is not observed. Cramping pains in the ab-

FIG. 391. A child 7 years of age with pseudohypertrophic muscular dystrophy, showing characteristic manner of rising from the floor. The last picture shows the standing position with the marked lordosis.

domen and in the muscles of the lower extremities are common. There may be mottling and cyanosis of the skin of the legs resulting from inadequate venous return, secondary to loss of muscle tone. In late stages of the disease tachycardia may be noted.

These children are usually cheerful, bright and hopeful despite the disabilities and long periods of invalidism consequent to the disease. Learning capacities are usually unimpaired, though mental deficiency is an occasional accompaniment.

A variant of the pseudohypertrophic form is the simple hereditary *atrophic form of Leyden-Moebius*, which is not associated with pseudohypertrophy and is stated to progress more slowly.

**Facioscapulohumeral form (type of Landouzy and Déjerine).** In this type the onset usually occurs between the ages of six and twenty years. Hereditary transmission follows a mendelian dominant pattern. The muscles first affected are those of the face and the shoulder girdle. The first defect often noted is inability to raise the arms above the head. The face becomes expressionless and mask-like, the patient being unable to close his eyelids, lift his eyebrows or wrinkle his forehead.

The process progresses slowly and over a period of years spreads to muscles of the pelvis and lower extremities.

**Juvenile muscular atrophy (type of Erb).** The onset of this type of the disease usually occurs in adolescence or early adult life. The muscles of the shoulder girdle are first affected, winging of the scapulas resulting because of atrophy of the serrati magni and the trapezii. There is difficulty in elevating the arms above the head. The muscles of the face are not involved. The disease is slowly progressive, the patient's condition often remaining unchanged for years.

**Diagnosis.** The clinical signs and characteristics of progressive muscular dystrophy which are important in differential diagnosis are the symmetrical and proximal distribution of muscular weakness, pseudohypertrophy, slow progression of the disorder, absence of sensory changes and the occurrence of the disease in other members of the family. In contrast, polyneuritis is associated with muscular weakness and atrophy of the extremities accompanied by pain, tenderness and sensory changes. Muscular weakness in spinal muscular atrophy is present at birth or appears early in infancy. Progressive neural

muscular atrophy involves the distal muscles of the extremities and of the hands. It is also associated with fibrillary tremors and electrical changes of degeneration.

**Prognosis.** The disease is progressive, death usually occurring within five to ten years of the onset in the pseudohypertrophic form. Few patients survive adolescence. Intercurrent infection is the most common cause of death. In rare instances myocardial insufficiency may be the terminal event.

**Treatment.** There is no specific therapy. Various amino acids, vitamins and hormones have been used in the treatment of this disease. Although encouraging therapeutic results have been reported, no therapy has proved to be beneficial. Efforts at supportive treatment are also of little avail. Orthopedic appliances and surgical procedures have been used in attempts to correct the contractures which develop late in the disease, but any benefit derived is temporary. Since inactivity seems to be accompanied by increased disability and deformity, it is important to utilize and exercise the muscles in which any degree of function remains. If other illnesses intervene which require periods of bed rest, massage and electrical stimulation may be used as a substitute for exercise.

A tendency to obesity in these children is common, and, unless dietary control is practiced, overweight may inflict an unnecessary disadvantage on the muscularly handicapped child.

## MYASTHENIA GRAVIS

**Etiology.** Myasthenia gravis is characterized by abnormal fatigability of skeletal muscle. The etiology is unknown. The defect seems to be manifest in the myoneural junction; there is either an insufficiency of acetylcholine at this site or an elevation of the threshold of the motor end plates with consequent partial block to incoming nerve stimuli. Neostigmine decreases the fatigability of affected muscles, as do other inhibitors of cholinesterase.

**Pathology.** There are no consistent gross or microscopic morphologic changes in the affected muscle. However, aggregates of small round cells, lymphorrhages, are often found in the skeletal muscles. Hyperplasia of the thymus or thymoma is present in some instances.

**Clinical Manifestations.** The disease is uncommon in infants and children. The first

manifestations may be ptosis or difficulties in mastication, speech and swallowing. Later the defect may extend to muscles of the neck, trunk and extremities. The affected muscles may be capable of contraction only for brief intervals or respond in limited extent to attempts to utilize them. Muscular response also tends to be weaker as the day progresses. Relaxation of facial musculature results in an appearance of apathy or lack of expression, often referred to as the "myasthenic facies." Involvement of muscles of mastication and deglutition may cause regurgitation of food through the nares or lead to episodes of choking. It may be impossible for the patient to climb stairs, walk, sit up or arise from bed when the muscles of the trunk or extremities are affected. Death may result when there is involvement of the muscles of respiration.

There is no muscular atrophy, and fibrillary contractions are absent. The deep reflexes are depressed or absent, and superficial reflexes are unimpaired. Electrical excitability shows no qualitative changes, but on repeated stimuli the muscles soon fail to respond (myasthenic reaction), although response may again be elicited after an interval of rest.

*Myasthenia gravis in the newborn infant* may be a transitory manifestation in an infant of a mother with the disease, or it may represent the onset of myasthenia in infants of nonmyasthenic mothers.

The clinical manifestations in the transitory disturbance in infants of myasthenic mothers tend to be severe, and death may occur. These infants respond promptly to neostigmine, but within a matter of weeks recover spontaneously, and no further treatment is necessary.

Much less frequently myasthenia gravis may be congenital in origin with manifestations present at birth or shortly thereafter, but usually of a much less serious order than is the case in the transitory disturbances. The course is progressive, however, and continuous therapy is needed.

Ptosis, a weak cry, hypotonia and easy fatigability, especially manifest in nursing, are common signs. It is likely that many instances of myasthenia of each of the foregoing types are mistakenly diagnosed as birth injury or narcotization.

Whenever an infant has hypotonia, with or without associated respiratory disturbances at or shortly after birth, which is not readily explainable by other cause, a therapeutic trial

with neostigmine would seem to be indicated. It is mandatory in infants of myasthenic mothers.

**Diagnosis.** The diagnosis is indicated when there is rapidly developed fatigue of skeletal muscle without atrophy, which is corrected in whole or in part by neostigmine. Bulbar paralysis, encephalitis and muscular dystrophy may need to be considered in the differential diagnosis.

**Prognosis.** The disease is chronic and is accompanied by remissions in which symptoms are alleviated or entirely absent for intervals of several weeks to years. Death may result from respiratory obstruction due to food particles lodged in respiratory passages or from respiratory failure when the muscles of respiration are affected. Infections are a hazard for these patients, since muscular weakness is exaggerated at such times. Malnutrition may result from difficulties in deglutition.

**Treatment.** Partial or complete relief from symptoms may be afforded by treatment with neostigmine. The drug may be administered orally as the bromide in doses of 5 to 15 mg. two to four times daily. It may also be given parenterally as the methyl sulfate; 0.5 to 1.5 mg. represents usually effective dosage. The drug, when administered subcutaneously or intramuscularly, will be effective within a few minutes, whereas effects are noted following oral administration after an interval of thirty to forty-five minutes. Tolerance to neostigmine may develop after prolonged treatment and it may become necessary to increase the dose. The amount of the drug administered should be carefully regulated to provide maximal comfort for the patient without excessive dosage. Undesirable side effects of neostigmine may be relieved with atropine. A number of other effective drugs are also available. Pyridostigmine bromide is said to have less undesirable effects on the gastrointestinal tract than neostigmine, and ambenonium chloride a more prolonged action. The anticholinesterase compounds, tetraethylpyrophosphate (TEPP) and octamethyl pyrophosphoramidate (OMPA) are said to provide more evenly sustained strength.

The occasional association of thymoma or thymic hyperplasia with myasthenia gravis has led to treatment by thymectomy or irradiation of the thymus. Such treatment should be reserved for patients not readily controlled by medical therapy or for those having a very large gland, when there is reason to believe it might be a thymoma.

The use of the respirator or tracheotomy may be lifesaving when the muscles of respiration and of swallowing are severely affected.

## FAMILIAL PERIODIC PARALYSIS

This syndrome is characterized by recurring attacks of flaccid paralysis of variable extent associated with a defect in potassium metabolism. The muscles are not trophic, and there is no muscular weakness in the intervals between attacks.

The disorder is relatively uncommon. It is a genetic disorder, occurring with equal frequency in both sexes. Many persons within a family may suffer from the disorder with manifestations of varying severity in different members. The trait may be transmitted through either parent as a dominant or a simple recessive character.

**Clinical Manifestations.** The disorder is usually manifest in childhood. Initial episodes of paralysis rarely occur after puberty. Attacks are most likely to develop during the night or after periods of inactivity. The patient may awaken to find himself paralyzed. The proximal muscles of the extremities are first affected, often followed by involvement of most of the voluntary musculature.

Paralysis may involve only a few muscle groups or may be total. Sphincter muscles and muscles of the face, eyes and tongue are not affected. During episodes of paralysis, tendon reflexes are depressed, and there is failure to respond to galvanic or faradic stimulation. Between attacks tendon reflexes and electrical excitability are normal.

Paralytic episodes are likely to follow excessive intake of liquids or carbohydrate foods, exposure to cold or injection of epinephrine or insulin. Patients may recognize symptoms which herald an attack and predict its occurrence hours in advance. Headache, somnolence, excessive thirst, fatigue or vague pains may occur as prodromes. A single paralytic episode may last from a few hours to two or three days. The intervals between attacks vary from a day or two to many years. The level of serum potassium at the onset of attacks varies, but decreases of 10 to 30 per cent are usual. The decrease is apparently the result of a shift of potassium from blood to the extravascular compartments. There is no increase in urinary potassium preceding an attack, but it is regularly observed as the paralysis recedes.

**Prognosis.** Death may occur during an initial or subsequent paralytic episode, either

from respiratory or cardiac failure. There is a tendency to reduction in the number and severity of attacks after middle life.

**Treatment.** Administration of potassium salts will control or abort a paralytic episode and will prevent occurrence of attacks. For terminating paralysis, 5 gm. of potassium chloride should be given orally, and this dose may be repeated in fifteen to thirty minutes if necessary. In severe paralytic seizures 50 cc. of a 2 per cent potassium chloride solution may be given intravenously. Recovery occurs usually before there is any perceptible increase in the potassium level. Recurrences are prevented in most patients by the daily ingestion of 2 to 4 gm. of potassium chloride. It is advisable to administer the drug at the time of retiring.

# The Skin

It is often possible to arrive at the diagnosis of a dermatosis and prescribe therapy with little help from the history. This situation is particularly advantageous in dealing with infants or young children who cannot transmit subjective complaints. The importance of the history from the mother or attendant or from an older child himself is not to be underestimated, however. The family history is particularly important when dealing with an allergic disease of the skin such as atopic eczema or a parasitic infestation such as scabies.

The cooperative activity of the dermatologist and the pediatrician and, on occasion,

the allergist is often necessary for accurate diagnostic appraisal and for satisfactory therapeutic results.

The child's skin is more sensitive to topical applications than is an adult's skin, so that drugs incorporated in a prescription for topical use must be correspondingly diluted. Roentgen therapy, valuable in the management of many dermatoses in adults, must be used sparingly and with caution on the skin of a growing child, not only because of local dermal effects, but also because of the potential dangers to underlying tissues, such as the epiphyses of bones and glandular structures.

## CONGENITAL AND HEREDITARY ANOMALIES AND DEFECTS\*

### NEVI

Two groups of nevi are recognized: (1) the vascular group, due to hyperplasia of the blood or lymph vessels; and (2) the nonvascular group, in which there is an overgrowth of epidermal or connective tissues.

#### NEVUS VASCULOSUS (see also p. 1358)

Vascular nevi are congenital formations composed chiefly of blood vessels and are often referred to as "birthmarks," although they may not appear until some time after birth. It is best not to interfere with the simple, flat type, commonly seen at birth, particularly in the occipital region; the majority disappear spontaneously.

The *nevus flammeus*, or *port-wine mark*, which is always flat, does not respond well to any known method of treatment. The slightly elevated so-called *strawberry mark* or *nevus* (Fig. 392) responds well to carbon dioxide snow or dry ice, which is used in the form of a pencil of the exact size to fit the

lesion and is held upon it with moderately firm pressure for five to forty seconds. Additional treatments may be given at intervals of three to four weeks. After each treatment a daily dressing of zinc oxide ointment or other bland emollient such as hydrophylic petrolatum, U.S.P., is advisable. Radium therapy is effective, but, unless it is given with great care, pigmentation or telangiectasia may appear years later.

There are distinct differences of opinion as to the advisability of treating strawberry nevi during infancy and early childhood, inasmuch as many disappear spontaneously. Some progress, however, and, since best results are obtained early, treatment can be considered by the experienced therapist.

*Angioma cavernosum* is treated most effectively with irradiation, by injection of sclerosing solutions, a combination of the two, or by surgery.

The earlier treatment is applied after the appearance of any type of elevated vascular nevus, the better the result, since the lesions tend to grow with the child. Death has been

\* See also page 338.

reported from hemorrhage following the rupture of neglected cavernous nevi, although occasionally trauma may result in spontaneous involution.

#### NEVUS PIGMENTOSUS

(MOLE) (See p. 1361)

LYMPHANGIOMA (See p. 1359)

#### ICHTHYOSIS

Ichthyosis is a congenital, hypertrophic disease characterized by dryness and scaling of the skin. In the winter the condition becomes more marked, the skin exhibiting scales which may be small and thin or large and thick, producing a "fish-skin appearance." Though cures cannot be expected, proper therapy will partially control the manifestations and make the patient more comfortable. Treatment consists in infrequent bathing using a superfatted soap and inunction of the skin with a greasy ointment such as one composed of 2 to 5 per cent salicylic acid in hydrous wool fat, hydrophilic petrolatum or goose grease. Relatively large doses of vitamin A may be given during the winter months, but toxic doses should be avoided.

#### KERATOSIS PALMARIS ET PLANTARIS

These lesions occur, usually symmetrically, as warty thickenings in the palms and soles. They may be hereditary or acquired. The condition is intractable, but improvement will result from the constant use of an ointment containing 5 to 25 per cent of salicylic acid in a lanolin base.

#### EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa is a rare hereditary disease of the skin in which vesicles and bullae develop from slight trauma. In its most severe form, designated as epidermolysis bullosa dystrophica, the mucous membranes are involved, nails are absent or deformed, and

FIG. 394. Ichthyosis.

the teeth may be abnormal and some may be absent. The fatality rate is high in such cases. When the mucous membrane of the oral cavity is involved, management of the child is exceptionally difficult. Lesions may be produced by eating coarse foods and then interfere with eating. The lesions usually appear during infancy, and in some instances mild defects disappear during adolescence. Occasionally a case has not become manifest until adulthood. Nothing will prevent the development of the lesions except avoidance of trauma. When a vesicle or bulla forms, it should be punctured and a sterile dressing applied. Antibiotic therapy is indicated when secondary infection occurs.

### CONGENITAL ECTODERMAL DYSPLASIA

This disease is characterized by incomplete development of the epidermis or its appendages or its absence in certain areas (Fig. 395). There may be several or all of the following: dental aplasia; congenital absence of the sweat glands (anhidrotic type); partial absence of the pilosebaceous apparatus; a dry, white, smooth, glossy skin; sparseness of the hair; alteration of the nails; and a characteristic facies, including prominent supraorbital ridges, a depressed nasal bridge, and eyes that slant upwards. The condition is familial, more commonly affecting males.

FIG. 395. Congenital ectodermal dysplasia. Dysplasia of single tooth erupted, with paucity of eyebrows and eyelashes. (Courtesy of Dr. Reuben Friedman.)

The first manifestation in early infancy may be an otherwise unexplained high fever secondary to high environmental temperature. Children with the anhidrotic type suffer severely during hot weather, and heat strokes may result from prolonged exposure to high temperature. Relief may be obtained by keeping the skin wet by sponging, spraying the clothing or by immersion in water.

### PACHYONYCHIA CONGENITA

Pachyonychia congenita is a rare congenital anomaly characterized by dystrophy of the nails, anomalies of the hair, hyperkeratosis of the palms and soles, and bullous lesions occurring most commonly on the feet (Fig. 396). The nails appear to grow straight out

FIG. 396. Pachyonychia congenita with secondary infection.

from the nail bed and often must be removed surgically so that the fingers can be used effectively.

### XERODERMA PIGMENTOSUM

This is a rare disease which becomes manifest in childhood or rarely in later life, and is characterized by hyperpigmentation, atrophic areas, telangiectases and malignant growths. It is transmitted as a recessive character. Fatal termination from malignancy is the invariable result. Affected persons should avoid strong sunlight. Malignancies are readily apparent and should be removed as rapidly as they appear.

**CUTIS HYPERELASTICA**

(CUTIS LAXA, EHLERS-DANLOS SYNDROME, DERMATORRHEXIS)

This unusual condition is characterized by hyperelasticity of the skin, hyperflexibility of the joints, fragility of the skin capillaries, and

at times by multiple, freely movable, subcutaneous fatty nodules. Bleeding into and beneath the skin is, as a rule, easily incited by trivial trauma and may be extensive. As a result, the arms and legs are frequently covered with ecchymotic scars.

**PIGMENTARY CHANGES IN THE SKIN****ALBINISM**

In complete albinism the epidermal tissues, the hair and iris are devoid of pigment, the skin is preternaturally white, and the entire hair of the body is fine, silky and whitish. Photophobia and nystagmus occur as a result of absence of the protective pigment in the choroid, and are a considerable annoyance to the patient. The pupils appear red in reflected light.

**FRECKLES**

(LENTIGO)

Freckles are pinhead-sized to pea-sized, brownish or blackish pigmented macules. Some children have a special predisposition to freckling, which may at times be hereditary. There is rarely any indication for treatment, and it should usually be discouraged.

It consists in attempting to produce exfoliation of the epidermal cells containing the pigment, since permanent removal will usually result in scarring. Desquamation may be accomplished by the use of keratolytic agents in ointments or lotions.

**VITILIGO**

This is an acquired pigmentary affection characterized by variously sized and shaped whitish patches with hyperpigmented borders. The disease progresses slowly, becoming conspicuous only after a number of years, and usually persists through life. In children it sometimes disappears spontaneously. There is no specific treatment. Strong sunlight should be avoided, since it increases the pigment in borders, while the patches remain white.

**HYPERTROPHIES AND ATROPHIES****CICATRIX**

Depressed or raised scars result from deep injury or disease of the skin involving the papillary body of the corium. Depressed scars such as follow smallpox, chickenpox or pustular acne vulgaris cannot be entirely obliterated, although desquamation of the skin by various techniques, including dermabrasion, may bring about slight improvement. The appearance can be improved by cauterizing elevated scars to the level of the skin.

**KELOID**

A new growth of the connective tissue, which appears as a small pea-sized nodule and in subsequent years slowly increases in size,

may arise spontaneously, particularly in the Negro race, or may develop at the site of traumatic or infectious wounds. The lesion may be painful or pruritic. Good therapeutic results are possible with roentgen ray or radium therapy. Excision or electrofulguration is nearly always followed by recurrence and at times by an even larger growth.

**KERATOSIS FOLLICULARIS**

(DARIER'S DISEASE)

Keratosis follicularis is a rare disease in which pinhead- to pea-sized dark-colored, acuminate or rounded papules mark the sites of horny plugs embedded in funnel-shaped dilations of the pilosebaceous follicles. The le-

sions may be numerous and closely grouped. Treatment with large doses of vitamin A in a water-miscible preparation may be con-

sidered. The possibility of toxic effects from continued administration of large doses of vitamin A must be recognized (p. 363).

## DISTURBANCES IN THE SUBCUTANEOUS FAT

### SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

(ADIPONECROSIS SUBCUTANEA NEONATORUM, PSEUDOSCLEREMA)

This is a self-limited disease characterized by a patchy distribution of circumscribed areas of fat sclerosis, which involves especially the buttocks, the scapular region and the cheeks. Lesions do not occur on the abdomen, the palms or soles, the axilla or the inner aspects of the thighs. The involved areas are firm, usually movable and well demarcated. During resolution there may be central softening, and the lesion misinterpreted as an abscess. It has been believed that trauma is an important causative factor and that the low olein content of the subcutaneous fat of the newborn predisposes to the condition. Microscopic sections of the skin reveal necrosis of fat cells, an infiltration of epithelioid or giant cells, edema and thickening of the vascularized septums, absence of elastic tissue, and thickened, protoplasmic, needle-like crystals in forms of rosettes or sheaths in the spaces surrounding the fat cells.

No treatment is indicated, and under no circumstances should the lesions be incised. They recede spontaneously within three to four months, usually without causing significant atrophy.

### SCLEREMA NEONATORUM

(SCLEREMA ADIPOSUM)

Sclerema is a diffuse hardening of the subcutaneous tissues occurring in debilitated, especially premature, infants. It may appear at any time during the first weeks of life, and is especially prone to be associated with diarrheal disturbances and dehydration. The hardening of the subcutaneous tissues is usually first noted in the lower extremities, often in the calves, from which it rapidly extends upward. Ultimately it may involve the entire body surface with the exception of the palms, soles and scrotum. The skin is shrunken, smooth and cold. The areas of induration are extremely hard and do not pit on pressure,

resembling the tissues of a frozen cadaver. Though sclerema is often a terminal manifestation, recovery is possible.

Pathologically, the changes consist in a stearin-like hardness of the fatty tissue combined with dehydration; on cutting the tissue there is practically no escape of fluid. Histologically, fat crystals may be present, but sections often differ little from normal.

There is no specific therapy. Variable results have been experienced with the use of corticotropin (ACTH) and cortisone; though a clinical trial with one of them is justified, other aspects of therapy must not be neglected. Oxygen therapy is often necessary. In view of the possibility of an existing or acquired infection, broad-spectrum antibacterial therapy is indicated at least during administration of the adrenal steroid. Correction of any water and electrolyte imbalance is essential.

### SCLEREDEMA

(SCLEREMA EDEMATOSUM)

Scleredema is seen chiefly in weak and premature infants, and often in association with diarrheal disturbances. It usually begins on the second to fourth day of life as an edematous swelling of the dorsal surface of the feet, calves, thighs, mons pubis and also of the upper extremities and eyelids. The characteristic pitting which occurs on pressure disappears slowly. In contrast to sclerema neonatorum, there is an obvious increase of volume of the affected parts, and, in contrast to subcutaneous fat necrosis, there are never any sharply circumscribed lesions. The edema may be extensive or may involve only selected sites, particularly the feet. Death usually occurs in four to five days, though recovery is possible.

Pathologically, there are no characteristic changes other than intense edema, which may involve the skin, subcutaneous tissue and underlying muscles; nonspecific inflammatory changes may also be present.

There is no specific therapy (see under Sclerema Neonatorum).

## LIPODYSTROPHY

Lipodystrophy is characterized by progressive loss of subcutaneous fat from the face, neck, thorax and upper extremities, and occasionally by an increase in fat in the lower part of the body. The cause is obscure. The disease is insidious in onset, beginning usually between the ages of eight and ten years. It has followed acute infections, and occurs twice as often in females as in males. The increase of fat in the lower half of the body is apparently limited to the female. Both hypothyroidism and hyperthyroidism have been reported in patients with lipodystrophy. Harris and Reiser observed a patient whose serum fat increased after a meal with a high fat content and who also had creatinuria and a lowered dextrose tolerance.

Biopsy of atrophied areas reveals almost complete absence of subcutaneous fat tissue; that which remains has no unusual staining properties.

The onset and course of the disease are asymptomatic. There is no pain in the areas of fat atrophy as there is in Dercum's disease (adiposis dolorosa). The active phase of

FIG. 397. Lipodystrophy in a girl aged 9 years. Note emaciation of face and neck in contrast to fair nutrition of the remaining portion of the body.

atrophy extends over a period of weeks or months, but the effects persist. The skin and muscles of the diseased areas are normal. The appearance of the patient is typical: the face is gaunt and the cheeks are sunken, with numerous lines and wrinkles about the mouth (Fig. 397). The arms or thorax may likewise appear emaciated, but the lower extremities are normal or may appear to have an increased amount of subcutaneous fat. This increase may be due to an increased food intake in a fruitless attempt to overcome the wasting of the face.

There is no specific *therapy*. The disease has no effect on life expectancy.

## RELAPSING NODULAR NONSUPPURATIVE PANNICULITIS

### (WEBER-CHRISTIAN SYNDROME)

The Weber-Christian syndrome is characterized by recurrent febrile episodes during which nonsuppurative nodules develop in the subcutaneous tissue. The condition is infrequent at any age and rare in children; nothing is known of its etiology. The lesions appear to be limited to the panniculus. Microscopically, the more or less circumscribed lesions reveal infiltration of the fatty tissue by large numbers of leukocytes and phagocytosis of fat cells by macrophages, which have a foamy, vacuolated appearance.

Relapses or "attacks" occur in completely irregular fashion. There may be single or multiple lesions, which develop rapidly and vary in size from less than a centimeter to several centimeters. The nodule may be painless or only slightly tender, is movable and usually distends the overlying skin, which is red or violaceous. The nodules may occur on any part of the body. During the active phase there may be a low grade fever, or the temperature may be as high as 104° F. The nodules may regress within a few days or may persist for several weeks; they usually do not leave any visible evidence, but there may be dimpling of the skin. The white blood cell count may be within normal limits, or there may be a leukopenia.

The *prognosis* must be guarded, since several fatalities apparently attributable to the disease have been reported. Recurrence is the rule, although recoveries or complete remissions are observed. No therapeutic agents, in-

cluding corticosteroids, have been effective. The *treatment* is entirely symptomatic, but must include guidance for the child and his family in their adjustment to the situation.

## DISEASES OF THE SEBACEOUS GLANDS

### MILIUM

The lesions appear as small, round, yellow or pearly-white sebaceous concretions just beneath the epidermis and are most common upon the forehead and cheeks. They occur commonly in infants and children and may be present at birth, but the cause of their formation is unknown. The lesions in infants or very young children disappear spontaneously, but in adolescents they must be incised with a fine scalpel and the contents liberated.

### ADENOMA SEBACEUM

Adenomas of the sebaceous glands may be present at birth or may appear shortly afterward. The lesions are pinhead- to pea-sized, rounded, elevated papules or nodules, situated particularly upon the nose, cheeks and chin. The color may be that of normal skin, waxy or reddish, and there may be an associated telangiectasia. Adenoma sebaceum frequently occurs in association with tuberous sclerosis (q.v.), in which mental deficiency is a prominent feature. Carbon dioxide snow applied over the affected areas for ten to twenty seconds with light pressure will often cause their disappearance. Larger lesions may require electrodesiccation.

### ACNE VULGARIS

Acne is an inflammatory disease occurring in and around sebaceous glands, characterized initially by comedones (blackheads) and later by superficial and deep papules and, if neglected, by pustules. The forehead, cheeks and chin are the regions usually affected, although the chest, shoulders and back may be involved. The disease is essentially one of adolescence and represents an overactivity of the sebaceous glands; more sebaceous material is formed than can be eliminated. It dilates the gland and pore, which becomes darkened from chemical changes and ingrained dirt, providing an ex-

FIG. 398. Acne vulgaris.

cellent culture medium for bacteria. Resulting abscesses may be deep and lead to eventual pitting and scarring.

The etiology is unknown. The most important consideration in management is early treatment. In cooperative patients this will prevent the lesions from producing disfiguring scars, thus avoiding social and personality disturbances.

. Constitutional *treatment* consists in improvement in general health through attention to diet (p. 151), sleep and other hygienic factors. Menstrual disorders (p. 155) may provide additional evidence of the need for such guidance. Avoidance of chocolate is generally recommended.

Local therapy is of great importance. The skin must be kept scrupulously clean by frequent use of soap and water to remove dirt and bacteria, and at bedtime this should be followed by the free application of a lotion such as lotio alba or the following modification of it:

	Gm. or Cc.
Zinc sulfate .....	4.0-6.0
Sulfurated potash .....	2.0-4.0
Rose water .....	120

Numerous flesh-colored proprietary lotions and creams containing sulfur compounds are also readily available.

If the skin is oily, 70 per cent alcohol or acetone may be applied before the lotion. Vitamin A may be given orally during the winter months in generous doses, but avoiding potentially toxic ones. These measures, rigorously adhered to, will control the lesions in many cases. Permanent cure cannot be expected during adolescence, but the treatment

should never be left entirely to time and nature, or scarring will inevitably result.

When these measures do not control the sebaceous overactivity, roentgen therapy is used at times. It should be reserved for extreme situations, and treatment must be provided by an experienced physician who is thoroughly aware of the potential dangers. Natural sunlight is often beneficial if not overdone, as is ultraviolet light if given in sufficient amount to produce mild erythema and desquamation. If scarring results from deep-seated postular lesions, the depth of the scars can often be lessened by dermabrasion.

## DISTURBANCES OF THE HAIR

### ALOPECIA

A physiologic or pathologic deficiency of hair, either partial or complete, is termed alopecia. *Congenital alopecia* commonly manifests itself either as scanty growth, a lack of development only in certain areas, or as a retarded appearance of the hair. Rarely is there complete absence of the hair due to arrested development of the follicles. Such cases are usually hereditary, and there may be delayed or defective dentition as well as other evidence of ectodermal dysplasia.

### ALOPECIA AREATA

This disease is characterized by loss of hair from round or oval patches; in rare instances these areas coalesce and produce total baldness. The scalp, eyebrows, eyelashes and, at times, the entire cutaneous surface may be affected (*alopecia totalis*). The patches are rounded; the skin is smooth and soft with a dead white or faintly pink color and is totally devoid of hair. Alopecia areata may develop suddenly or gradually and spread by peripheral extension until it reaches a certain size, when it tends to remain stationary. The disease usually persists for several months, during which time the hair tends to return gradually. The hair almost always grows back in children except in the totalis type, which is often persistent. When regrowth occurs, the

FIG. 399. Alopecia areata.

patch is first covered by fine downy, whitish hairs, which later change into coarser pigmented ones. The etiology is unknown. Many of these children are emotionally disturbed prior to the alopecia. It has been suggested that there may be a causal relationship.

*Treatment* consists in improving physical and emotional health. Dried brewers' yeast or vitamin B complex has been thought to be beneficial. Local measures such as daily massage of the patches with a 0.1 to 0.25 per cent anthralin ointment and erythema doses of ultraviolet rays from a mercury quartz lamp are believed to hasten regrowth of hair.

# DRUG ERUPTIONS

## (DERMATITIS MEDICAMENTOSA)

Skin eruptions may be produced by a number of drugs and serums. Table 116 shows the skin reactions to some of the common drugs.

Table 116. Drug Eruptions

<i>Drug</i>	<i>Type of Eruption</i>	<i>Drug</i>	<i>Type of Eruption</i>
Acetanilid.....	Erythematous	Iodides.....	Acneiform, bullous, erythematous, urticarial, papular, purpuric; may resemble erythema nodosum
Aminopyrine.....	Urticarial	Penicillin.....	Morbilloform and urticarial; angioedema
Arsenic.....	A wide variety of eruptions; at times much pigmentation or exfoliation	Phenolphthalein..	Erythematous, urticarial, bullous, macular; resembling erythema multiforme
Barbiturates.....	Maculopapular to morbilliform; urticaria; purpura; erythema multiforme; exfoliative dermatitis	Quinine.....	Scarlatiniform, urticarial, purpuric, bullous, ulcerative; sometimes with desquamation
Belladonna (atropine).....	Scarlatiniform, urticarial	Salicylates.....	Erythematous, scarlatiniform, purpuric; resembling erythema multiforme; sometimes with desquamation
Bismuth.....	Scarlatiniform or urticarial, with pruritus	Streptomycin....	Urticaria
Bromides.....	Acneiform, vesicular, pemphigoid, ulcerative, large papules, pustular, ecthymatous (Fig. 400). Mucous membranes may be involved. There may be excretion of bromides through breast milk	Sulfonamide....	Morbilloform, exfoliating dermatitis, urticaria
Chloral.....	Scarlatiniform, papular, urticarial, purpuric, lichenoid	Tetracyclines....	Urticaria; angio-edema chiefly from chlortetracycline
Digitalis.....	Scarlatiniform, papular		
Ephedrine.....	Erythematous, purpuric		

FIG. 400. Bromide eruption. Ecchymatous eruption following administration of potassium bromide.

## DERMATITIS AND ECZEMATOID LESIONS\*

Dermatitis, or inflammation of the skin, a term restricted to acute inflammations which result from known irritants, is characterized by heat, redness, pain and swelling. The term "eczema" is used interchangeably with derma-

titis, but is generally limited to cases which tend to be persistent or recurrent, irrespective of whether the cause is an external or internal one. Eczema may be considered a syndrome with numerous etiologic possibilities.

\* For infantile eczema, see page 1312.

**DERMATITIS VENENATA****(ALLERGIC CONTACT DERMATITIS)**

Dermatitis venenata includes the group of inflammatory conditions caused by vegetable and mineral irritants. Most common in children is the dermatitis produced by poisonous plants, chiefly poison ivy (*Rhus toxicodendron*) and poison oak (*Rhus diversiloba*). Poison sumac, dogwood, ash and the primrose may also cause a contact dermatitis, and there are many other rarer plants and shrubs which irritate the skin. From a few hours to several days after exposure the hands, face and other exposed areas of the skin become the seat of innumerable vesicles and blebs, accompanied by redness, swelling, burning and intense itching. The vesicles may appear in linear streaks, and the eruption may be carried to other parts of the body, particularly the genitals, by auto-inoculation. Some persons are so highly susceptible that direct contact is not required, the poison apparently affecting them if they are in the proximity of the plants. At times the poison may be brought into the house on the fur of a cat or dog and communicated to the child who fondles his pet. Some persons enjoy comparative immunity, although it may disappear any time during life.

Immunization against the dermatitis of poison ivy is a controversial issue. If desensitizing injections of ivy extract are given, they should be administered in early spring in a

single dose or in multiple doses according to the manufacturer's instructions. They are protective, if at all, for only one season.

*Treatment* of the acute rash with ivy extract is contraindicated.

In the active case of dermatitis venenata, no matter what the cause, relief of itching is the paramount consideration, since, unless it is relieved, more damage will be done by scratching than by the disease. Corticosteroids, if used early either locally or systemically, seem to be beneficial. If they are used systemically for more than a day or so, an antibiotic should be prescribed to combat infection. Quick relief is usually obtained by hot compresses of liquor aluminum acetate (Burow's solution) in a strength of 4 tablespoonfuls of the concentrated solution to 1 quart of hot water, followed by the free application of the following lotion:

	Gm. or Cc.
Sodium thiosulfate.....	8.0
Resorcin and boric acid, of each.....	4.0
Glycerin.....	4 to 8
Zinc oxide powder.....	30.0
Witch hazel.....	60.0
Distilled water, to make.....	180.0

Potassium permanganate compresses (1:4000 or approximately one 5-grain tablet in a quart of water) and numerous other types of solutions have been recommended. When edema is present, continuous hot compresses should be used during waking hours until the edema completely subsides, which may be several days.

**SEBORRHEIC DERMATITIS**

In infants the so-called cradle cap is believed to be a type of seborrhea; it occurs on the scalp either as a thick, greasy crust or as thin, dry scales. In older children seborrhea in its simplest form is manifest as ordinary dandruff, representing a normal though excessive exfoliation of the epidermis, which may be dry or oily, according to the type of skin. When this scale, for reasons not well understood, becomes marked, it is frequently infected by bacteria. In this stage seborrheic dermatitis may involve the scalp, ears, eyebrows and lashes, angles of the nose, or the cheeks and even the trunk.

*Treatment* must be directed primarily to the scalp. A simple ointment of sulfur precipitate, 1 gm., and salicylic acid, 0.6 gm., in 30 gm. of petrolatum or Aquaphor applied nightly and accompanied by a scalp shampoo

FIG. 401. Dermatitis venenata (*Rhus toxicodendron*).

which includes selenium sulfide (Selsun) for a dry scalp or tellurium dioxide (Teles) for an oily scalp, once or twice a week often suffices to free the scalp of scale. A mixture of equal parts of crude oil and olive oil with a daily shampoo may also be used. On non-hairy areas an ointment of sulfur precipitate, 0.3 gm., and salicylic acid, 0.2 gm., in 30 gm. of petrolatum often brings about rapid improvement. Ointments combining an antibiotic and a corticosteroid are effective for seborrheic dermatitis involving nonhairy areas.

### INFECTIOUS ECZEMATOID DERMATITIS

Ecematoid conditions are occasionally produced by the irritation from purulent secretions from abscesses, discharging sinuses, eyes or ears. The lesions may be dry and scaling, vesicular or pustular, and crusted. The application of bacitracin or tetracycline ointment

may bring about rapid improvement, provided the purulent discharge is no longer permitted to irritate the area. If extensive crusting is present, a starch poultice (see Formulary, p. 1301) will be useful in removing the crusts, after which one of the above-mentioned ointments may be used. Any simple ointment, such as petrolatum, may be applied to prevent irritation from purulent discharges.

### LEINER'S DISEASE

(ERYTHRODERMA DESQUAMATIVUM)

Leiner's disease is usually associated with an exudative diathesis, especially a seborrhea of the scalp. The onset is usually in the second or third month of life. The lesions appear first about the buttocks and the gluteal folds and extend over the remainder of the body. The skin is red and covered with grayish-white scales, which at first are opaque, but later become somewhat lustrous (Fig. 402).

FIG. 402. Leiner's disease. Note plaquelike scales on chest. (Hill, in *Practice of Pediatrics*, edited by McQuarrie. W. F. Prior Co., Inc.)

FIG. 403. Ritter's disease.

There is often an eosinophilia. Vomiting and diarrhea, cyanosis, hypertonia and eventually cachexia are prominent symptoms. The prognosis in general is favorable. The treatment is symptomatic.

### ITTER'S DISEASE

(DERMATITIS EXFOLIATIVA NEONATORUM)

Ritter's disease usually develops in the first few weeks of life as a local hyperemia of the cheeks and around the corners of the mouth, from where it spreads to involve all the body. Quickly there is wrinkling of the skin and desquamation of it in sheets, leaving large, denuded, reddened, dry areas. *Nikolsky's sign*

(easy removal by friction of undenuded skin) is characteristic, but not pathognomonic. There is usually no fever. There may be a leukocytosis with a mononucleosis. Sections of the skin are characterized by desquamation, cellular infiltration and edema. The case fatality rate was about 50 per cent before the advent of antibacterial therapy. The prognosis is now much more favorable.

It has been questioned whether Ritter's disease and Leiner's disease are separate entities, since there is some overlapping in both the clinical and the pathologic manifestations. The clinical patterns are distinct, however; Ritter's disease appears to be infectious in origin, whereas Leiner's disease has elements suggestive of an allergic etiology.

## ERYTHEMATOPAPULAR AND SQUAMOUS ERUPTIONS

### PSORIASIS

It has been estimated that about half of the cases of psoriasis begin in childhood. The disease is uncommon before the age of ten, and extremely rare under three years of age. Heredity seems to be a factor in a small percentage of cases. Psoriasis almost invariably begins as small, reddish, pinpoint- to pinhead-sized papules, surmounted by minute scales. The patches increase by peripheral extension, becoming a centimeter or more in diameter. The individual patches in the well developed case are dry, round, sharply defined, more or less infiltrated and elevated, and covered with profuse, shining, gray or whitish mica-like scales. When the scales are removed, a reddish base is exposed, on which there may be one or more punctate hemorrhages. The sites of predilection are the scalp and the extensor surfaces of the elbows and knees, although the eruption may occur in patches over the trunk and extremities. The nails may show pitting. Constitutional symptoms are lacking, but there may be a variable degree of itching.

Psoriasis pursues, as a rule, a chronic course, although at times the eruption may disappear spontaneously. Recurrence, however, may be expected throughout life. The cause is not known; psoriasis is not contagious.

*Treatment* is at times successful in clear-

ing an individual attack, but permanent cure is not obtained. If the patient can be hospitalized, the Goeckerman method of treatment is best.

On the first day all the patches of psoriasis are covered thickly with an ointment consisting of 2 to 4 per cent crude coal tar, 2 per cent zinc oxide and 50 per cent corn starch in petrolatum, which is left on overnight. The following morning it is removed with light mineral oil, a thin layer of oil being left on the skin. Ultraviolet light is then applied for one minute at 30 inches after dividing the skin surface of the body into six areas, each of which is treated as a unit. The time of exposure is increased and the distance of the lamp from the skin is decreased daily to maintain the skin in a state of mild erythema. After each light treatment the patient spends one-half to two hours in an oatmeal bath, which loosens the scales. After the bath another thick coating of ointment is applied to the skin, particularly over the patches; another coat is applied before retiring. This program is continued daily until no psoriatic scales remain and there is little or no induration in the patches. Autohemotherapy, consisting in withdrawing 10 ml. of blood from a vein and immediately injecting it into the gluteal muscles, is also given five times at intervals of two days, but one may doubt its value.

The most important point in the ambulatory treatment of psoriasis is the recognition that the eruption has a cyclic course, a stage of activity or evolution followed by quiescence. In general the disease is more active during the winter months.

Best results from local therapy are achieved

FIG. 404. Psoriasis.

during the quiescent phase. The scales must first be removed by a thorough scrubbing with soap and water or by application of a soft ointment containing 2 per cent each of ammoniated mercury and salicylic acid. Chrysarobin is then applied in a strength varying from 1 to 10 per cent, or a chrysarobin derivative such as anthrarobin, which may be purchased as Anthralin ointment. It should not be used for children in concentrations greater than 0.1 to 0.25 per cent. Ointments must be thoroughly rubbed into the patches. If a dermatitis results from the application, a bland ointment may be substituted temporarily. Roentgen therapy is used for obstinate patches, but probably has no place in the therapy of children. Ultraviolet light therapy is of value only after a crude coal tar ointment has been applied the previous evening and partially removed with warm oil before the exposure. Natural sunlight is beneficial, but overexposure must be avoided. Recently beneficial results have been observed with the use of Kenacort or Aristocort.

### PITYRIASIS ROSEA

Pityriasis rosea is a self-limited inflammatory disease of the skin characterized by pink or

reddish erythematous patches appearing chiefly on the trunk, upper arms, and thighs, and at times accompanied by a mild constitutional disturbance. A primary or herald patch may precede the eruption by a few days to a week. The eruption appears fairly rapidly as minute lesions which enlarge peripherally to a centimeter or so in diameter. Often the patches are oval, their long axes

FIG. 405. Pityriasis rosea (showing herald patch).

following the lines of cleavage of the skin. Slight, branny scaling is usually present. Itching is absent or moderate, although, particularly at night, it may be severe. The cause of pityriasis rosea is unknown.

The disease is noncontagious. For the relief of itching a lotion consisting of liquor carbonis detergens, 15 cc., and calamine lotion (see p. 1301) sufficient to make 180 cc. (6 ounces) is useful. The patches of pityriasis rosea rarely appear in areas of suntanned skin, and ultraviolet light therapy at times seems to shorten the course of the disease. Untreated, the average case clears up spontaneously in about six weeks. With treatment, however, the eruption may disappear within two or three weeks.

## KERATOSIS PILARIS

The extensor surfaces of the arms and thighs are the usual sites of this disorder, which is characterized by closely aggregated, pinhead-sized, conical elevations corresponding to the orifices of the hair follicles. The skin is dry and rough and has the feeling of a fine nutmeg grater when the finger is passed over it. Some cases appear to be due to a vitamin A deficiency, and treatment should include vitamin A in doses of 25,000 to 50,000 units daily. A simple ointment consisting of 10 parts of cocoa butter and 90 parts of cold cream massaged thoroughly into the skin will soften the dry patches.

# INFECTIONS OF THE SKIN

## BACTERIAL INFECTIONS

### IMPETIGO CONTAGIOSA

For Impetigo Neonatorum, see page 339.

Impetigo contagiosa is a localized, superficial infection of the skin, caused most often by the *Staphylococcus*, less often by the *Streptococcus*, and characterized by vesicles which quickly become purulent, rupture and form crusts. Usually by the time the physician sees the child the crusts, which have the appearance of being lightly "stuck on" the skin, predominate; but close examination may reveal unruptured lesions, particularly if no treatment has been applied (Fig. 406). The disease spreads rapidly among contacts. The sites of predilection are the face, ears and nares, but any part of the skin, including the scalp, may be involved. Mild itching is the only symptom. At times several lesions may become confluent with central healing, or a large bulla may rupture and heal centrally, but show continued activity at the border. This type of lesion is known as *impetigo circinata*. When the lesions spread peripherally with irregular contours, they are termed *impetigo gyrata*. So-called *Bockhart's impetigo* is usually limited to the scalp, where the lesions are discrete follicular pustules, but it may also occur on the upper and lower extremities. When lesions of impetigo border the scalp, a search should be made for pediculi.

The differential diagnosis of impetigo is

rarely difficult. The circinate and gyrate types may be mistaken for *tinea circinata*, but the lesions of the latter are more uniformly circular, consisting of scaling patches with tiny peripheral vesicles, and they do not have the exudative, crusted appearance of impetigo. In

FIG. 406. Impetigo contagiosa gyrata.

*pustular eczema* the patches are deeper, larger and more diffuse and are accompanied by itching. The lesions of *ecthyma* are considerably deeper and are covered with a thick, hard crust.

The *treatment* of *impetigo contagiosa* is not difficult, but must be carried out carefully and conscientiously to achieve quick results. When there are only a few lesions, local treatment is sufficient, but when there is extensive involvement, as, for example, of most of the face or scalp, or when lesions are widely distributed over the body or when local lesions do not respond to surface therapy, systemic antibiotic therapy is indicated. In such instances penicillin administered orally or intramuscularly, or one of the tetracyclines or erythromycin by the oral route is apt to be effective.

Local treatment consists in removing the crusts in such a manner that bleeding is avoided, the opening of unruptured pustules with a sterile needle, and the application of bacteriocidal ointment. The use of hot compresses or starch poultices will frequently facilitate the removal of crusts. The ointment should be applied immediately and repeated sufficiently often to keep the lesions completely covered. For local therapy it is preferable to select antibiotics, such as bacitracin or neomycin, which are infrequently used systematically.

## ECTHYMA

Differing from *impetigo* only in that the lesions are more deep-seated and therefore likely to leave pigmentation and slight scarring, *ecthyma* is characterized by discrete, flat, deep pustules which dry with heavy crust formation. It is believed that either streptococci or staphylococci may produce *ecthyma* when introduced into such lesions as scabies, pediculosis, insect bites or deep scratches, particularly when the hygiene is poor.

*Treatment* consists in both general and local measures. The general hygiene should be corrected, and an adequate diet, including essential vitamins, should be provided. Otherwise the treatment is that described for *impetigo*.

## FURUNCULOSIS

A furuncle begins as a painful, deep-seated infection of a sebaceous gland or hair follicle

and gradually approaches the surface, appearing as a rounded or acuminate, reddish prominence. In a few days softening takes place, with formation of a central slough or core. Slight, usually temporary, scarring follows. The invading bacteria are almost invariably staphylococci. When the lesions are multiple and occur in crops, they are termed "furunculosis."

*Treatment* of a single furuncle should be conservative, consisting of dressings of 10 to 25 per cent Ichthammol ointment or any other mildly antiseptic ointment until softening is complete, when it will usually rupture spontaneously; if necessary, the furuncle may be incised. When a series of furuncles appears, the urine should be examined to determine whether diabetes is present, though there is no close relationship.

Emphasis should be placed on a diet containing generous amounts of fresh fruits and vegetables, eggs, milk and meat. In severe cases staphylococcal toxoid or an autogenous vaccine may be used. Frequent application of 70 per cent alcohol to the skin surrounding the lesions may help in preventing spread of bacteria to neighboring follicles. Preparations containing hexachlorophene are also useful in this respect and for cleansing the skin. Lesions of the face, particularly of the nose and upper lip, should never be incised or traumatized. Hot, wet compresses of a saturated magnesium sulfate solution applied for fifteen to sixty minutes three or four times in twenty-four hours or continuously during the daytime will ultimately cause the lesions to open and drain. If the compresses are applied intermittently, the lesion may be dressed during the interim periods with a 10 or 20 per cent Ichthammol ointment. Systemic administration of an appropriate antibiotic is indicated for severe and generalized furunculosis.

## FURUNCULOSIS IN INFANTS

Debilitated infants as a rule have a low resistance to infection and frequently acquire infections of the skin. Extensive furunculosis involving the scalp, back and posterior portions of the extremities occurs occasionally in such infants. There are usually systemic disturbances, such as fever, anorexia and toxemia. In the more severe instances response to treatment is poor and relapses are frequent. *Treatment* consists in attention to fluid, electrolyte and other nutritional re-

quirements and in systemic antibiotic therapy. The case fatality rate has been ma-

terially reduced in recent years by such therapy.

## *Tuberculosis of the Skin*

For Erythema Nodosum, see page 1300.

Cutaneous tuberculosis is rare in the United States. The tubercle bacillus may invade the skin directly through an abrasion (primary infection), by continuity from an underlying tuberculous lesion such as that of a lymph node, or by hematogenous distribution. Cutaneous lesions such as tuberculides and erythema nodosum may also be produced by circulating toxins of the tubercle bacillus.

### **LUPUS VULGARIS**

Lupus vulgaris frequently begins in childhood as numerous pinpoint- to pinhead-sized, grouped or disseminated, reddish, yellowish or brownish, flat papules. When compressed by a glass slide, the papules are reddish-brown. Gradually they enlarge to form tubercles or nodules which in turn coalesce into variously shaped and sized pustules. Although extension continues slowly, the older lesions may disappear by absorption, leaving a scaly, atrophic scar, or they may ulcerate, form crusts and eventually heal with a residual scar. The disease is chronic and may persist into adult life with considerable disfigurement. A type occurring in children, known as *multiple disseminated lupus vulgaris*, consists of multiple, small, discrete nodules or patches which appear suddenly and are scattered over the cutaneous surface. Lupus vulgaris may be associated with other types of skin tuberculosis such as tuberculosis verrucosa cutis, scrofuloderma or tuberculous ulcers, and with visceral, bone, joint and pulmonary tuberculosis.

*Treatment* of lupus vulgaris should be both constitutional and local. A high vitamin diet, fresh air and controlled exercise are recommended. Specific antituberculous therapy with isoniazid in conjunction with para-aminosalicylic acid is the treatment of choice at this time (see p. 465 for dosage). Local treatment has for its object the extirpation of the lupus tissue with as little resultant scarring as possible. Individual nodules or small patches may be thoroughly destroyed by electrofulguration under local or general anesthesia. Larger patches are best treated with

the Finsen lamp, but this is not obtainable in the United States.

### **TUBERCULOSIS VERRUCOSA CUTIS**

Inoculation of the tubercle bacillus into the skin from without may produce one or more warty vegetations which occur most commonly on the hands. The lesion begins as an inflammatory vesicopustule or papule and slowly increases in size, and the surface becomes encrusted. When the inflammation is marked, pus may be expressed from the crypts. When healing occurs, a smooth, scaly scar remains.

The lesions are easily destroyed by electrofulguration under local anesthesia. Carbon dioxide snow, pyrogallol acid ointment and roentgen therapy have also been used.

### **SCROFULODERMA**

This lesion begins in one or more lymph nodes or in bone and extends to the surface to involve the skin in a true tuberculous process. When lymph nodes are involved, they are initially swollen and painful, but later undergo caseation and suppuration and form sinuses which discharge a caseous, sanious pus. The resultant skin involvement appears as an oval or linear ulceration with violaceous, undermined edges and an uneven base with pale, flabby granulations. The surface may be crusted. (See p. 467 for treatment.)

### **PRIMARY TUBERCULOUS LESIONS**

#### (TUBERCULOUS CHANCER)

Tubercle bacilli may invade the skin or mucous membrane through abrasions; the intact skin is not vulnerable. The resemblance of the primary lesion to a syphilitic chancre is at times striking. The common sites are the lip (Fig. 407), nose, chin, extremities and genital region; there is an accompanying involvement of the regional lymph nodes to complete the primary complex. The initial lesion may occur as a dark red papule, a small crusted ulcer with an elevated border or as a small plaque. Tubercle bacilli may be found in the skin lesion and in the lymph nodes; the histologic findings are those of

FIG. 407. Primary tuberculous lesion.

tuberculosis. Excision of the primary lesion and of the lymph nodes is indicated if they are in appropriate sites. Antibacterial therapy should be used if excision is performed and in other instances if the lesion appears to be progressive (see p. 467).

### LICHEN SCROFULOSORUM

These lesions are pinhead-sized, firm, yellowish-brown or reddish nodules. The nodules

coalesce into coin-sized patches and are situated chiefly on the trunk. They may be accompanied by slight itching. The course is chronic, although the prognosis is favorable. Treatment consists in specific therapy for any systemic tuberculous infection and in measures to improve the general health, which include a diet with a high vitamin content, especially of vitamin D.

### TUBERCULIDES

Tuberculides are thought to be caused by the toxins of the tubercle bacillus, the most common type in children being the papulonecrotic tuberculide. The lesions, which appear in crops, are pea-sized or smaller, firm, bluish-red papules, crusted at the summit. When the crust is removed, there is a crater-like depression. Search should be made for the primary tuberculous focus, which is usually in the lungs.

*Treatment* consists in improving the general health by means of fresh air, sunshine, vitamin D and an adequate diet. Antimicrobial therapy is indicated for the systemic tuberculous infection (see p. 464).

## Lupus Erythematosus

The two principal varieties of lupus erythematosus are *chronic discoid lupus erythematosus* and *systemic lupus erythematosus* (see p. 925).

In the chronic discoid variety the early lesions are rounded or oval pinhead- to pea-sized erythematous, slightly raised areas which increase in size either by peripheral extension or by coalescence of neighboring lesions. Fully developed, the disease appears as one or several sharply margined, reddish or violaceous patches, varying from a half-inch to several inches in diameter. The surface is covered with thin, white or gray scales, which are usually adherent and extend deeply into the sebaceous glands. The border of the patch is slightly elevated, and the center tends to atrophy. There is some infiltration and thickening of the patch. Occasionally, especially in children, the disease spreads symmetrically over the nose and cheeks, creating the outline of a butterfly with wings spread. Subjective symptoms of moderate itching and burning may be present. The sites of predilection are the face, particularly the

nose, cheeks and ears, and less often the scalp, lips and buccal mucous membranes. When inflammation is marked and there is no atrophy, the term "subacute" may be applied.

In children the *treatment* of lupus erythematosus of the discoid type is important, since healing may be obtained, although the scars usually persist. Among the drugs used are chloroquine diphosphate, quinidine hydrochloride (Atabrine), quinine, potassium, para-aminobenzoate (PABA), bismuth and gold. In general it is preferable to try the least toxic drugs first, such as chloroquine, PABA or Atabrine. The yellow discoloration of the skin resulting from treatment with Atabrine is a deterrent against its use. Dosages of these drugs are as follows: chloroquine, 0.25 to 0.5 gm. twice a day; Atabrine, 50 to 100 mg. three times a day; and PABA, 0.1 to 0.2 gm. per pound of body weight per day in six divided doses during the waking hours.

Gold therapy is now rarely used and is definitely contraindicated in the more inflammatory (subacute) types.

In all types of lupus erythematosus, exposure to strong sunlight must be strictly avoided, and a protective (sun screen) lotion

or cream should be applied even for minimal exposure.

## FUNGUS INFECTIONS

Fungi are responsible for a number of different skin diseases which include the various types of ringworm, favus, pityriasis versicolor and moniliasis.

### RINGWORM

(TINEA)

A number of the subvarieties of both the small-spored and the large-spored groups of fungi are of etiologic significance in ringworm. The most important of the small-spored group is *Microsporum audouini*, which causes about 90 per cent of the cases of ringworm of the scalp in children and apparently affects only human beings. *Microsporum felinum* and *Microsporum lanosum* produce ringworm of the human scalp and skin. Microsporiasis occurs in cats, dogs, horses and other mammals and may be contracted by children from any of these animals. The large-spore fungus or trichophyton is responsible for most of the varieties of ringworm of the hairless skin.

### RINGWORM OF THE SMOOTH SKIN

Customarily, ringworm of the skin other than the scalp is known as (1) tinea circinata, (2) tinea cruris or (3) ringworm of the hands and feet. In tinea circinata the lesions are situated most often upon the face, neck, hands and forearms. In children with the microsporon type of scalp involvement, patches may extend just beyond the hair margin on the neck or forehead, but should not be confused with tinea circinata. Tinea circinata begins as one or several rounded or slightly irregular pea-sized, reddish-pink, slightly raised, scaly patches. Peripheral spreading and central clearing progress simultaneously; a well developed patch may be 1 or more cm. in diameter, and the outline is that of a ring, from which it receives its common name, ringworm (Fig. 408). Itching may be present, but is usually mild.

*Tinea cruris* is a variety of tinea circinata, but the clinical appearance may be modified by perspiration and by bacterial contamination. The lesions appear upon the upper and

inner surfaces of the thighs, and may also involve the scrotum, the anal fold and the buttocks. Initially, the appearance of the lesions is identical with that of circinata, spreading peripherally with a tendency to central clearing. Local warmth usually causes an exaggeration of the inflammation and itching, and secondary bacterial infection may cause the patches to be studded with pinhead-sized pustules. In the treatment of the inflammatory stage the following formula, applied freely three times in twenty-four hours, is recommended:

	Cc. or Gm.
Bichloride of mercury.....	0.060
Witch hazel water.....	30
Calamine lotion (U.S.P.) (with or without phenol), to make.....	180

After the inflammation has subsided Whitfield's ointment (U.S.P.XV) or the following formula may be applied twice daily.

Salicylic acid.....	2.0
Benzoic acid.....	4.0
Castor oil.....	30 cc.
Isopropyl alcohol (50%) to make.....	120 cc.

### RINGWORM OF THE HANDS AND FEET

Ringworm of the foot, popularly termed "athlete's foot," is the most common of all types of fungus diseases. A similar eruption may occur on the hands. There are also eruptions (dermatophytids) of the hands, legs and trunk associated with ringworm infection of the feet, which are probably caused by absorption of toxins from the local lesions.

Three types of eruptions appear on the feet: (1) intertriginous, involving the inter-spaces of the toes and having a dry or sodden, scaly and fissured appearance; (2) acute vesiculobullous, which more commonly occurs on the soles and sides of the feet; and (3) chronic thickened and hypertrophic, in which the skin is thickened and covered with scale formation. Secondary bacterial invasion of fissures may result in lymphangitis, cellulitis, phlebitis or erysipelas.

Treatment of ringworm of the hands and feet depends upon the type of eruption. In the intertriginous type one of the following

FIG. 408. Tinea capitis and tinea circinata.

methods may be used: (1) soaking the feet in a 1:4000 hot solution of potassium permanganate, (2) painting daily with Castellani's paint, (3) the daily application of Whitfield's ointment (U.S.P.XV), or (4) an ointment containing zinc undecylenate and undecylenic acid in a vanishing cream base applied morning and night. Strong applications should never be used initially. After the scales have been removed and the fissures have healed a dusting powder may be used for several weeks to guard against recurrence and to keep the interspaces dry. Several proprietary powders have found favor, such as Desenex, Timofax, Korium and Epto, or the following may be used:

	Gm.
Salicylic acid.....	1.0
Benzoic acid.....	2.0
Starch.....	10.0
Talc.....	16.0

In the *acute vesicular* and *bullous types* the patient or parent should be taught to open the lesions aseptically, after which the feet should be soaked in a 1:4000 hot solution of potassium permanganate for twenty minutes, twice daily. A 1:15 dilution of Burow's solution (made by adding 4 tablespoonfuls of Burow's solution to 1 quart of hot water) may be used instead of the permanganate. Only after the acute phase has subsided are stronger parasitocidal remedies to be prescribed, but, to prevent recurrence, it is advisable to apply Whitfield's ointment

(U.S.P.XV) until the dead skin is entirely removed. Socks must be boiled, and shoes and slippers may be sterilized by placing a piece of blotting paper soaked in 4 per cent formalin on the inner soles for twenty-four hours, followed by exposing them to the open air and sun for another twenty-four hours.

In the dry, *squamous, noninflammatory* or *hypertrophic type*, Whitfield's ointment (U.S.P.XV) may be used from the beginning. If the thickening of the skin is marked and the scale heavy, ointments containing 10 to 25 per cent salicylic acid may be required for exfoliation. The hypertrophic form is rare in children. Roentgen therapy should never be used during the acute stage, and, although helpful in subacute or chronic stages, its use should probably be restricted to the most severe cases in older children and adults. Dermatophytids will usually disappear after effective treatment of the primary focus. Relief of itching may be obtained by the frequent application of Schamberg's calamine lotion (see p. 1301).

#### RINGWORM OF THE SCALP

(TINEA TONSURANS, TINEA CAPITIS)

This type of ringworm, which is practically limited to children, begins as small rounded, reddened, scaly patches. Typical lesions consist of practically bald, discrete, rounded, coin-sized, slightly reddened patches covered with grayish scales and broken hairs (Fig. 408). The hairs in a patch are lusterless and

consist of broken stumps. They lie loosely in the follicles and are easily extracted. Rarely, the scalp may be diffusely involved without production of circumscribed patches.

In *tinea kerion* (pustular tinea) there are raised, boggy or edematous patches, honey-combed with distended openings of hair follicles, through which a yellowish pus exudes. The suppuration hastens the cure, but may lead to scarring and to permanent baldness.

Mild itching is the only common symptom of ringworm of the scalp, but when kerion is present, there may be tenderness and pain. Most cases are caused by *Microsporum audouini* or *Microsporum lanosum*.

Clinical recognition is not difficult. A positive diagnosis is made by examination under a beam of ultraviolet light passed through a Wood's filter (glass containing nickel oxide) or by microscopic examination of extracted hairs. For the latter the hair is prepared by immersion in a 20 per cent solution of potassium hydroxide and examined without staining. Abundant spores which have a fish roe appearance are seen on the hair. Diagnosis of the exact type of fungus is made by culture on maltose agar.

Infections caused by *Microsporum lanosum* are cured by local remedies, such as petrolatum, containing 1 per cent each of iodine crystals, thymol and oil of cinnamon, a 10 per cent ammoniated mercury ointment or a salicylanilide ointment.

When infection is due to *Microsporum audouini*, local applications alone are rarely adequate. Though the infection tends to disappear spontaneously at puberty, epilation is usually necessary to obtain a cure in the more resistant cases during childhood. If this is done manually, the scalp is washed thoroughly with soap and water, as many hairs as possible are removed with depilating forceps, and a parasitocidal ointment is rubbed in for ten minutes. An ointment containing 5 per cent of salicylanilide and 95 per cent Carbowax is efficacious in some cases, but usually fails to cure completely. Better results can be expected if daily extraction of infected hairs is performed under a Wood light at home in conjunction with continued local application of the ointment. A skull cap made of a material that may be boiled is worn continuously to prevent spread of the infection to others. Roentgen epilation is effective, but the possibilities of affecting the pituitary gland or osseous growth centers and of causing permanent baldness are serious

deterrents. During the bald period parasitocidal ointments must be continuously applied. Epilation by means of thallium acetate is to be condemned.

## FAVUS

(TINEA FAVOSA)

Caused by *Trichophyton schoenleini*, tinea favosa is rare in the United States and is seen chiefly in immigrants. In children the lesions are chiefly on the scalp and consist of one or several small, yellowish patches which enlarge and may form sulfur-yellow cups, or scutulae, from each of which a hair projects from the depressed center. Scarring is associated with permanent alopecia. The treatment is the same as for the more resistant types of ringworm of the scalp.

## PITYRIASIS VERSICOLOR

(TINEA VERSICOLOR)

Pityriasis versicolor is an uncommon disease in children, but when untreated may last for months or years. Caused by *Malassezia furfur*, it is characterized by pinhead- to pea-sized, yellowish-brown macules which slowly increase in size and coalesce with the formation of large brownish patches whose surfaces are covered with a fine, furfuraceous, mealy scaling. Mild itching is usually present.

Treatment consists in washing thoroughly with soap and water, followed by the application of an ointment composed of 1.0 to 1.5 gm. of precipitated sulfur and 0.6 gm. of salicylic acid in 30 gm. of an emulsion base. The applications should be made daily and continued for two weeks after the eruption has disappeared from the surface of the skin. Solutions of sodium hyposulfite (4 cc. in 30 cc.) or of bichloride of mercury (0.6 cc. in 30 cc.) are easily applied, and either one is effective.

## MONILIASIS

(CANDIDIASIS)

Many eruptions of the skin formerly diagnosed as eczema are monilia infections. Monilia are frequently found in the vaginal secretions of pregnant women, and in this way infants may be infected. Oral lesions are not infrequent, but lesions of the skin are rare. Finnerud cultured scrapings from the angles of the mouth of 100 children with perlèche and found organisms believed to be cryptococci or Monilia in 77 per cent. Whether these

organisms were primary or secondary invaders was not established.

The skin in moniliasis may show a disseminated, papulovesicular, scaling eruption or localized intertriginous lesions.

A weak iodine solution (1 per cent tincture) or an ointment containing 1 per cent of salicylic acid and 2 per cent precipitated

sulfur in an emulsion base may be used on the skin. Gentian violet in a 1 per cent aqueous solution is effective but unsightly. It may be removed from clothing with spirits of ammonia. Among the newer agents, Nystatin may be used systemically and locally, and amphotericin B locally for cutaneous moniliasis.

## PARASITIC INFESTATIONS

For Bites and Stings of Other Insects or Parasites, see page 598.

### SCABIES

See also page 599.

Scabies results from infestation of the skin by *Acarus* or *Sarcoptes scabiei*, commonly called the itch mite, which is barely visible to the naked eye. The female parasite burrows in the epidermis, deposits her eggs and, in doing so, produces a burrow or cuniculus which appears as a tiny, straight or tor-

tuous, grayish or blackish, linear elevation. At the point of entrance a small vesicle or pustule is often seen. The most common sites for burrows are the webs of the fingers and flexor surfaces of the wrists. The lesions can often be identified only with a magnifying glass. In well developed scabies there may be seen, in addition to the burrows, a multi-form eruption consisting of papules, vesicles, crusts, excoriations and thickening. The sites of predilection for the more advanced cases are the interdigital spaces, the flexor surfaces of the wrist and arm, the axillary folds, the nipples of the female breast, the umbilicus, the buttocks, the penis and the toes (particularly in infants). In young infants the eruption may be so severe as to resemble eczema. Facial lesions are rarely observed except in nursing infants whose mothers have scabietic lesions on the breasts.

Itching is intense, particularly at night, and secondary inflammation results from the unavoidable scratching. Secondary infection is common and may be manifested as impetigo, ecthyma or furunculosis. Pyodermia of the hands should always cause the examiner to search for evidence of scabies (Fig.

FIG. 409. Scabies. (Courtesy of Dr. Reuben Friedman.)

FIG. 410. Scabies. Note linear pattern of individual lesions.

FIG. 411. Scabies involving genitals. This is a common site of infection, and one that is often missed. (Courtesy of Dr. Alex Steigman.)

FIG. 412. Scabies with secondary infection.

FIG. 411. Scabies involving genitals. This is a common site of infection, and one that is often missed. (Courtesy of Dr. Alex Steigman.)

409). Untreated scabies may last indefinitely with no tendency to spontaneous healing. Though the clinical *diagnosis* is usually not difficult and may often be substantiated by the history of other cases in the family, it can be made at times only by finding the parasite. By using a sharp razor blade it is not difficult to remove an entire burrow, which is then placed in saline solution or tap water on a glass slide and examined microscopically with a low power objective. Diagnosis may be made upon recognition of a whole or any part of an *Acarus*, of an ovum or fecal matter. Diagnosis may be simplified by examination of the infant's mother or attendant.

The objects of *treatment* are destruction of the parasite and alleviation of the accompanying dermatitis. The *Acarus* is easily destroyed by such remedies as sulfur, beta-naphthol, balsam of Peru, styrax, oil of cade, pyrethrum, rotenone and benzyl benzoate.

Benzyl benzoate in concentrations of 10 to 30 per cent is available in proprietary formulas as an emulsion and an ointment. It has the advantages of being rapidly effective and of clean application. The usual method of application is to cover all affected areas with the preparation immediately after a bath while the skin is still moist. As soon as this application has dried, a second one is made. Twenty-four hours later a second bath is taken with soap and water. Dermatitis may occasionally occur. If itching continues and there is no evidence of dermatitis, another

application of benzyl benzoate should be made five to seven days later.

Carpenter has used an emulsion consisting of:

	Gm. or Cc.	Concentrated Preparation Gm. or Cc.
Benzyl benzoate.....	10.0	68.0
DDT.....	1.0	6.0
Benzocaine.....	2.0	12.0
"Tween 80".....	2.0	14.0
Water, to make.....	100.0	—

The concentrated preparation is diluted with 5 parts of water before use. The emulsion is applied by spraying. A single spraying is usually sufficient, but three or four may be necessary. This emulsion is both scabicial and ovacidal. Among the newer effective preparations are creams of benzene hexachloride (Kwell) and of crotomyl-N-ethyl-o-toluide (Eurax). The body is covered with either one twice daily for three days and then again for three days one week later. Clean clothes and bed clothing should be used after each three-day course and the soiled clothing thoroughly cleansed.

All members of the family should be treated simultaneously.

If itching persists after the disease has been eradicated, Benadryl or Pyribenzamine may afford considerable relief.

PEDICULOSIS

There are three varieties of *Pediculus*: *P. capitis*, head louse; *P. corporis*, body louse; and *P. pubis*, crab louse.

PEDICULOSIS CAPITIS

This disease, caused by *P. capitis*, is characterized by severe itching of the scalp. The

resulting scratching leads to the formation of excoriations with serous, purulent or sanguineous exudation, which dries and forms crusts and mats the hair together. A foul odor is usually present. From the secondary infection in the scalp the postcervical nodes may become involved and in some cases suppurate. Scattered papules, impetiginous crusted lesions, pustules and excoriations are frequent about the face and neck. Pediculi are present on the scalp in varying numbers, and the ova or nits are in abundance. The ova are grayish, translucent, oval bodies attached to the hair by a membranous sheath. They hatch out in three or four days.

To be effective, *treatment* must destroy the pediculi, devitalize the ova and allay the inflammation. Crude petroleum oil, either pure or mixed with an equal quantity of olive oil, is effective; it should be thoroughly applied to the scalp for one or two nights followed each morning by a shampoo with plain soap and water or tincture of green soap and water. Frazer recommends an emulsion containing DDT, 2 per cent; naphtha, 15 per cent; emulsifying agent, 5 per cent; and water, 78 per cent, worked thoroughly into the scalp with a paint brush. This is left on overnight and combed out the following morning. A simple measure for removal of the ova is to comb the scalp daily with a fine comb dipped in hot vinegar (dilute acetic acid). Recovery of the more heavily infested cases may be hastened if the hair is cut short. Creams of benzene hexachloride (Kwell) and of crotonyl-N-ethyl-o-toluide (Eurax) are effective against both the parasite and the ova. When

there is pustulation around the margins of the scalp, bacitracin ointment may be applied.

### PEDICULOSIS CORPORIS

Pediculosis corporis, rare in children, is produced by a parasite larger than the head louse. It resides in seams of underclothing where ova are deposited. The louse is present on the skin only when foraging. Ova hatch in about six days. The itching in pediculosis corporis is intense; as a result, examination of the person shows chiefly excoriations or long scratch marks. Close examination will reveal hemorrhagic points where the pediculi have extracted blood. Transitory wheals, small papules and localized infections may also be present.

*Treatment* consists primarily in disinfection of the clothes and bed linens. Cleaning the clothes and pressing them with a hot iron will destroy ova and parasites. Bed linen should be boiled. For the relief of itching a lotion of 2 to 5 per cent carbolic acid in olive oil may be prescribed.

### PEDICULOSIS PUBIS

This disease is almost exclusively observed in adults. The author has seen only one case in a child, and, as commonly happens, the parasites and ova were found on all hairy areas except the scalp. In children the eyebrows are particularly likely to be involved. One application of Cuprex usually suffices for a cure. Five per cent DDT powder in talc dusted over the infested area is also an excellent and clean remedy.

## VIRAL INFECTIONS

### VERRUCAE

#### (WARTS)

Commonly known as a wart, a verruca is a pinhead- to bean-sized circumscribed elevation of the skin due to epidermal and papillary hypertrophy. Various types are distinguished: (1) *verruca vulgaris*, the common wart, which occurs as single or multiple lesions, most often upon the hands of children (Fig. 413); (2) *verruca plana juvenilis*, smooth, flat, slightly elevated, light brown lesions occurring chiefly on the face, neck and dorsum of the hands; (3) *verruca filiformis*, slender threadlike outgrowths occurring chiefly upon the face, eyelids and neck; and (4) *verrucae plantaris*, or plantar warts,

which somewhat resemble a callus and occur upon the sole of the foot. Plantar warts may occur singly or in groups and may be extremely painful. They have a characteristic appearance when the horny plate which covers them is removed. Warts are auto-inoculable and slightly contagious.

The *treatment* of warts is often unsatisfactory. Internal treatment is of doubtful value, but is occasionally attempted when a number of warts are present. In evaluating therapy it must be remembered that warts frequently disappear spontaneously, undoubtedly accounting for the multiplicity of medicinal treatments as well as those based upon superstitions and psychotherapy.

The best method of treatment for all types

FIG. 413. Verruca vulgaris.

of warts except possibly those on the sole, especially if there are only a few, is removal under local anesthetic. One per cent Novocain is injected beneath the growth, which is then thoroughly curetted and the base cauterized with 50 per cent trichloroacetic acid, actual cautery or electrofulguration. Care must be taken to trim off any overhanging edges that might promote secondary infection. Monochloroacetic acid and dichloroacetic acid are occasionally used to destroy warts, but must be applied with great care. Cauterization of a large number of flat warts may lead to disfiguring scars. Exfoliation by erythema doses of ultraviolet light should be tried before resorting to more radical therapy. Podophyllin (10 per cent) in tincture of benzoin painted carefully on the warts at weekly intervals occasionally is also effective, or the following prescription, which is applied to the wart once daily on a cotton applicator, may be tried:

Salicylic acid (5 per cent) . . . . .	1.5 gm.
Podophyllin (5 per cent) . . . . .	1.5 gm.
Tincture benzoin, q.s. ad . . . . .	30.0 cc.

Plantar warts are the most resistant to therapy. Successful results are usually obtained by removing as much of the growth as possible by means of 40 per cent salicylic acid plasters and then using roentgen or radium therapy on the remainder of the growth. Rarely, however, is radioactive therapy justi-

fied in children. Surgical removal is possible by using Eufocaine anesthesia, which usually prevents pain. The wart is scooped out with a curet, and a pressure bandage is applied after packing the wound with Terramycin powder and Gelfoam. There may be recurrence after any type of therapy.

### MOLLUSCUM CONTAGIOSUM

This is a slightly contagious, auto-inoculable disease characterized by pinhead- to pea-sized, elevated, smooth, waxy, semiglobular, white or pinkish lesions. First appearing as pinhead-sized, discrete, slightly elevated papules, the lesions gradually enlarge and develop a central depression or umbilication (Fig. 414). Pressure on the growth causes expulsion through this central area of a white, cheesy material. The number of lesions slowly increases until a hundred or more may be present.

*Treatment* consists in destroying the growth by incision followed by expression of contents and then by cauterization of the cavity with a stick of silver nitrate, with trichloroacetic acid or an electrocautery point. Boring each lesion with a pointed applicator stick dipped in pure phenol is a simple and often efficacious mode of treatment. New lesions should be destroyed as soon as they appear. They will often disappear without operation with the daily application of 10 per cent lactic acid and 10 per cent salicylic acid in a vehicle of flexible collodion.

FIG. 414. Molluscum contagiosum.

## THE ERYTHEMAS

The term "erythema" is commonly used to signify a hyperemia of the skin which may be localized or widespread and may be caused by external or internal factors. Pressure with the finger on an erythematous area will blanch the area momentarily. A number of clinical types of erythema are relatively common. The external types are (1) *erythema caloricum*, which results from exposure to extremely high or low temperatures; (2) *erythema solare* (sunburn), caused by exposure to the actinic rays of the sun; and (3) *erythema traumaticum*, due to cutaneous injury. The internal or toxic erythema, sometimes ineptly termed "stomach rash," may be associated with diseases which do not naturally have an exanthem and with certain drugs.

Severe sunburn may be treated with hot saline solution compresses followed by application of a bland ointment. Children who are to be exposed to the sun for prolonged periods of time should be thoroughly covered with a tannic acid and salol, or a quinine lotion or cream, of which there are a number of satisfactory proprietary preparations.

### MILIARIA RUBRA

(PRICKLY HEAT)

This is a common disturbance of infants and occasionally of older children and is perhaps best considered a sweat retention syndrome. It is characterized by small pinpoint- to pinhead-sized erythematous papules and at times vesicles. They appear after excessive heat from climatic or other external conditions such as excessive clothing. There is evidence of slight inflammatory changes surrounding the ducts of the sweat glands. This condition is closely related to sudamina. Any area of the body may be affected, but the face, neck, shoulders and chest are especially susceptible. Prophylaxis consists in avoidance of overheating by removal of clothes during periods of extreme heat, frequent bathing and the judicious use of an electric fan or air-conditioning unit.

*Treatment* is not particularly satisfactory. A bath with starch added (1 pound of lump laundry starch in a half-tub of lukewarm water) or Aveno powder, a proprietary made from oatmeal, followed by dusting the skin thoroughly with borated talcum powder or

other so-called prickly heat powder gives considerable relief. Calamine lotion containing 1 or 2 per cent phenol and 0.25 to 0.5 per cent menthol is often effective in allaying the itching.

### INTERTRIGO AND DIAPER RASH

Commonly known as chafing, this condition is common in children and occurs where two moist skin surfaces are in apposition, such as the groin and inner thighs, buttocks, flexures of joints, and neck. Moist and fecal-soiled diapers allowed to remain on the infant for relatively long periods are one of the common causes. Untreated, a dermatitis or eczema may be superimposed on the erythema, producing local heat and soreness.

*Treatment* consists in keeping the affected areas clean and dry. During the day infants with diaper rashes should be placed on their abdomens and an incandescent light placed over the exposed buttocks. At night the buttocks should be covered with zinc oxide or some other bland ointment. Simple talc or frequent dabbing with calamine lotion (p. 1301) usually suffices for the milder cases and for intertrigo in regions other than the diaper area. Strongly alkaline soap should be avoided in the washing of diapers, which should be thoroughly rinsed and dried.

The so-called *ammoniacal diaper rash* is characterized by erythema on the convex surfaces of the buttocks, without involvement of the opposed surfaces, and by papulovesicular

FIG. 415. Papulovesicular lesions of ammoniacal dermatitis.

lesions which, when broken, become umbilicated or crater-like (Fig. 415). In circumcised male infants there is often an associated ulceration about the external urethral meatus. The causative factor is the production of ammonia in the urine by urea-splitting bacteria which originate in the intestine and infest the skin about the buttocks. The ammonia is formed after the urine has been voided, and the odor is greatest after the wet diaper has been allowed to remain on the infant for several hours. Ammoniacal dermatitis is treated in the same manner as other diaper rashes, but its prevention is of the greatest importance.

The incorporation of an antiseptic in the diapers has proved an effective method to inhibit the growth of ammonia-producing organisms. A number of antiseptics have been used. They are added to the final rinse water; the diapers should then be wrung out lightly and allowed to dry. The commonly used antiseptics for home laundry have been bichloride of mercury and boric acid. Both are dangerous as poisons, and it is doubtful whether such a weak antiseptic as boric acid is effective. There are a number of commercial preparations, most of which have as their active ingredient a quaternary ammonium compound known as Hyamine 10X. This compound may also be bought in solutions of several strengths. The recommended dilution for a diaper rinse is 1 ounce of a 10 per cent solution in 4 gallons of water for 10 pounds of fabric; one dozen diapers weighs approximately 2 pounds. This compound is also toxic and should be kept out of the reach of children. At present the majority of commercial diaper laundries use phenylmercuric acetate in a concentration of about 1:150,000 as the antiseptic in their final rinsing solution.

## ERYTHEMA MULTIFORME

The skin manifestations of erythema multiforme may at times be preceded or accompanied by fever, malaise, rheumatoid pains and other constitutional disturbances. The eruption, which usually appears abruptly, may consist of macules, maculopapules or vesicles and blebs, although one type of lesion tends to predominate in an individual case (Fig. 416). There may be mild itching and burning. Sites of predilection are the dorsal surfaces of the hands, the forearms, the tibial regions, the face, and the back of the neck, but at times the eruption may be widespread.

The mucous membranes, as, for example, of the mouth, eye or genital region, may be involved. When the patches are circular with peripheral spreading and central clearing, the affection is called *erythema circinata*. Concentric rings of vesicles, particularly on the palms, are termed *herpes iris*. A form of erythema multiforme bullosum characterized by widespread lesions which also involve the mucous membranes and are associated with a severe form of conjunctivitis and constitutional symptoms with high fever, has been termed the *Stevens-Johnson syndrome*. Loss of sight is an occasional sequel.

The lesions of erythema multiforme tend to occur in crops and may persist for one to four weeks. In some instances there is a distinct tendency to recurrence, with frequent attacks over a period of years, but in general it is a self-limited disease. The *diagnosis* is based upon the acute onset of the individual attack, the multiforme quality of the eruption, the absence of severe itching, and the tendency to recurrence.

*Treatment* is symptomatic and should be directed at maintenance of fluid and electrolyte balance and of the general nutrition. The disease is self-limited. Antibacterial therapy is indicated only when there is a reasonable possibility of an associated bacterial infection. Corticosteroids are not curative, but

FIG. 416. Erythema multiforme bullosum.

FIG. 417. Erythema multiforme. Herpes iris type of eruption.

may suppress the manifestations and on such a basis are justified in acutely ill children.

### ERYTHEMA NODOSUM

This variety of erythema is rare in infants, but is relatively common in older children and adolescents. It may occur in the course of a number of different conditions, but is generally associated with primary tuberculosis, coccidioidomycosis and hemolytic streptococcal infections, including rheumatic fever. There are, of course, distinct geographic variations in the incidence of the basic diseases. The disease is usually ushered in with fever, localized pains, and malaise. Round or oval nodelike swellings, varying in size from a hazelnut to an egg, develop rapidly over the region of the tibia and less often on the forearms and thighs. The nodes are red, tense and shining, and exquisitely tender to the touch. At first hard, they gradually soften, but never ulcerate. They persist for a week to ten days, when the color and swelling gradually disappear.

The prognosis is favorable so far as the skin lesions are concerned, but the ultimate outcome depends on the underlying disease. Differentiation is chiefly from *erythema induratum*, in which the lesions are more commonly on the backs of the lower legs, are less acute in their evolution, and may ulcerate.

*Treatment* of an attack consists chiefly in rest in bed with the legs elevated. If the pain is severe, salicylates or other analgesics may be administered.

### URTICARIA PAPULOSA

(LICHEN URTICATUS)

For Urticaria, see page 1318.

This type of urticaria occurs exclusively in children and is distinguished by an eruption of papules which appear chiefly in the summer months. It has been suggested that insect bites act as a "trigger mechanism" to bring out the lesions of urticaria papulosa. These papules are about the size of a pinhead, or slightly larger, and are pale red; they are irregularly disseminated, most of them occurring on the trunk and extremities. They are preceded by a wheal which causes itching, particularly at night, often leading to the erroneous diagnosis of scabies. Unlike the lesions of scabies, they occur on the face and are rarely seen on the hands. The following lotion is recommended to relieve itching:

	cc.
Coal tar solution .....	15
Calamine lotion (p. 1301), to make .....	180

### URTICARIA PIGMENTOSA

Wheals develop which last for several weeks and then disappear, to be followed by brown-

ish macules. Sometimes the macules appear without any preceding wheals, and it has been suggested that some such cases probably belong in the category of nevi. Infants may occasionally present vesicles and bullae. The eruption is persistent, often beginning in infancy and lasting until puberty or throughout life. In rare cases the bones, the liver, the bone marrow and lymph nodes may be involved. Antipruritic lotions may be used for relief of itching.

PRURIGO

This is an inflammatory disease of the skin, characterized by pinhead- to pea-sized, pale red papules, occurring chiefly upon the extensor surfaces of the extremities, beginning in infancy or early childhood, lasting for years or throughout life, and accompanied by intense itching. As a result of the intense itching the affected areas are covered with excoriations and bloody crusts. After a time the skin becomes harsh, dry, thickened and, at times, pigmented. The neighboring lymph nodes, particularly those in the inguinal re-

gion, are often enlarged sufficiently to be visible. The disease is difficult to control, but fortunately is rare in the United States. *Treatment* consists in relieving the intense itching by means of Aveno baths and the application of an ointment containing tar or sulfur, and in improving the general health of the child.

HYDROA AESTIVALE (See also p. 280)  
(RECURRENT SUMMER ERUPTION)

This disease is vesicular and tends to recur each summer on the exposed areas of skin. Beginning usually in the second or third year of life, the disease tends to disappear after puberty. The eruption first appears as red macules upon which vesicles quickly develop singly or in groups. As the vesicles rupture, the lesions become crusted, and subsequently there is slight scarring. Symptoms of burning and itching are usually mild. The patient should avoid exposure to sun, wind and excessive heat. If crusting is marked, a bland ointment may be applied.

FORMULARY FOR DISEASES OF THE SKIN

Calamine lotion (Schamberg formula):

	GM.	OR	CC.
Resorcin and boric acid,			
of each .....	4.0		
Glycerin .....	4.0		
Calamine powder .....	30.0		
Witch hazel .....	30.0		
Distilled water, to make .....	180.0		

(Neocalamine powder may be used in place of calamine to approximate skin color.)

Starch poultice (for removing crusts):

Mix 1 tablespoonful of laundry starch, 1 table-  
spoonful of boric acid powder and 2 tablespoonfuls  
of cold water. Add 1/2 cup of boiling water, stirring  
constantly. Spread between thin layers of gauze and  
apply to area to be treated.

	GM.	OR	CC.
Coal tar paste:			
Coal tar and zinc oxide powder, of			
each .....	2.0		
Mix and add starch and petrolatum,			
of each .....	15.0		
Whitfield's ointment (for ringworm, noninflamma- tory):			
Benzoic and Salicylic acid ointment, U.S.P. XV			
Salicylic acid .....	1.0		
Benzoic acid .....	2.0		
Polyethylene glycol ointment .....	30.0		
Dusting powder:			
Zinc oxide powder .....	4.0		
Boric acid powder .....	4.0		
Starch .....	12.0		
Talc .....	12.0		

CARROLL S. WRIGHT

# Burns

Burns are among the most frequent accidental injuries of infants and children. Morbidity and mortality rates from these injuries exceed those from poisoning. Burns of infants and young children are incurred mostly in the home, whereas older children receive burns in their home, school and play activities. Thermal or chemical agents, electricity and exposure to ultraviolet rays, roentgen rays or radioactive substances are other factors responsible for burns.

Permanent disfigurement and disability and immediate and delayed mortality depend upon the extent of the surface area involved and upon the depth to which the burn penetrates. Even small burns involving the skin over joints may produce contractures which seriously limit motion. Death during the acute phase results chiefly from alterations in blood volume and from changes in the composition of the circulating blood. Plasma loss begins quickly after the burn and persists at least one or two days. In third-degree burns considerable destruction of the red blood cells occurs immediately in addition to plasma loss. Moreover, during the first week after the burn, renal damage of the lower nephron type may exaggerate these changes. Death after the first few days results from local or intercurrent infection and from debilitation.

The *treatment* of burns involving small and superficial areas of the skin is simple. The involved area is cleansed, and a sterile ointment is applied. White petrolatum (U.S.P.) or an ointment with a local anesthetic may be used. The local application of sulfonamides or boric acid ointment is not recommended. Sedatives and analgesics may be necessary.

Since second- or third-degree burns involving 12 per cent or more of the body area usually require hospital treatment, it is important to have an approximate estimate of the area of the body surface involved. The extent of the burn may be estimated according to directions on page 196.

Because shock always occurs with extensive burns, measures to prevent it should be in-

stituted promptly. The patient should be given morphine parenterally and placed on a sterile sheet; the burned areas should be covered with sterile towels until surgical care of the area can be undertaken. Blood from the patient should be obtained for hematocrit and hemoglobin determinations as well as for typing and crossmatching for transfusion. Plasma should then be administered intravenously until the results of these determinations are available.

Although there are no completely satisfactory formulas for calculation of the amounts of plasma, blood and electrolyte solutions to be administered, the method stated on page 195 is suggested. The amount of fluid calculated to be administered initially must be altered later in relation to subsequent laboratory determinations, urinary output and clinical appraisal of the patient. For extensive burns the amount of colloid solutions, especially blood, may be greater than calculated, whereas the amounts of physiologic saline solution may be less. In all instances of shock whole blood is preferred over all other solutions. Plasma is preferred over colloidal solutions such as dextran. If plasma which has not been irradiated to kill the virus of infectious hepatitis must be used, gamma globulin should be administered as a prophylactic.

The foot of the patient's bed should be elevated. No attempt to raise or reduce the patient's temperature is necessary. Oxygen may be given to combat restlessness and cyanosis. Tetanus toxoid or antitoxin and gas gangrene antitoxin may be given, and therapy with antibacterial agents may be instituted while preparations for surgical care are being completed.

There is considerable difference of opinion as to the advantages of the various types of local treatment. The production of an eschar by rapid coagulation with tannic acid has been discarded. Various substances containing antiseptic dyes or antibacterial agents which establish a film over the burned area have been used. These preparations would

seem to have their greatest usefulness when a burn has been untreated for thirty-six to forty-eight hours.

The pressure bandage method of Koch has gained considerable favor when early treatment is possible. The burned area should be carefully débrided and cleansed surgically. The entire burned surface is then covered with fine mesh gauze, such as rayon. This is covered with several layers of dry, coarse mesh gauze, and absorbent cotton or fluffed mechanic's waste is placed on top. Compression is then secured by tightly bandaging the entire dressing. Under ordinary circumstances this type of dressing is allowed to remain in place for two or three weeks. If there is an elevation of temperature or a foul odor from the dressing, however, it should be removed and treatment of the infected wound instituted. Some advocate the application of a light plaster of Paris cast instead of pressure bandages. Others perform no initial débridement, but administer antibacterial agents as prophylaxis against infection.

Wallace has treated burns by the open method, i.e., exposure to air, elevation of the burned area, immobilization and prophylactic antibacterial agents. No local irritants are applied, and dry heat, such as that pro-

vided by a cradle with an electric light, is avoided. Such a method of handling burns has considerable merit in the event of a civilian disaster.

Early grafting of skin is recommended when possible for deep or extensive burns. Other types of reconstructive plastic surgery may be necessary.

The importance of teaching children the hazards of fire cannot be overemphasized. Parents must exercise great care to keep hot objects beyond the reach of toddlers.

# Allergic Diseases

## GENERAL DISCUSSION

The term "allergy" was first used by von Pirquet to denote altered tissue reactivity. It is now generally used to describe those reactions resulting from antigen-antibody union within the living animal. The present concept of the allergic mechanism is that histamine or some similarly acting substance, produced when antigen and antibody unite within or on the surface of the cell, reacts in turn on the neuromuscular apparatus of the shock organ (skin, lung or other tissue) to produce the allergic reaction. The fundamental and characteristic allergic lesion is the urticarial wheal, which is the result of capillary dilatation, increased capillary permeability, and edema. There is a diapedesis of leukocytes, composed early of polymorphonuclear cells and later mostly of monocytes.

Much confusion surrounds the various conceptions of how human allergy is related to human and animal anaphylaxis (nonallergic sensitization). Both normal man and animals can be sensitized by the administration of foreign proteins; the nonallergic person absorbs antigen from his gastrointestinal tract in the same manner as does the allergic person. In addition, equal capacities for the production of antibodies from such specific antigenic stimulation as from typhoid vaccine have been observed in nonallergic and in allergic children by Rubin and Rapoport. Passive sensitization of the skin of normal persons by means of the passive transfer of antibody indicates that their cells have the capacity to become sensitized and, when antigen is injected into the passively sensitized site, to react to the union of antigen and antibody. The allergic reaction depends on the presence of antibodies produced by previous sensitization with an antigen (*active sensitization*). The anaphylactic response may be similarly brought about by the injection of preformed antibodies which sensitize the recipient to subsequent exposure to antigen (*passive sensitization*).

How, then, does the sensitized allergic

person differ from the sensitized nonallergic (normal) person? In an attempt to distinguish human allergy from anaphylaxis, Coca coined the word "atopy" to designate a constitutional response of certain persons to foreign substances, chiefly protein in nature. The constitutional factor in the allergic person appears to be inherited.

The chief distinguishing feature of the allergic person is the ease with which he produces, after antigenic stimulation, specific antibodies which can be demonstrated by passive transfer.

This type of antibody, known as the *atopic reagin* or *skin-sensitizing antibody*, is different from other antibodies which both normal and allergic persons develop in response to antigenic stimulation. The skin-sensitizing antibodies are more heat-labile, have a molecular weight higher than that of human gamma globulin, and do not readily traverse the placental barrier from mother to infant. In contrast, other immune antibodies developed in both normal and allergic persons in response to antigenic stimulation are heat-stable, are associated with the gamma globulins, are not firmly fixed in skin as are atopic reagins and are easily transmitted through the placenta.

The anaphylactic response may occur in animals and in man without the inherited constitutional factor, and is characterized in most instances by absence of passive transfer antibody.

The usual sensitizing component in antigen is protein. Carbohydrates, lipids and various chemicals may, however, by protein linkage (haptens), act as antigens to produce antibodies specific for themselves. It is also possible that certain of these substances in their *pure* forms may act as antigens.

Whether bacterial and viral hypersensitivity, which differs in many ways from the ordinary hypersensitivity to such antigens as egg white, is related to the peculiar structure of the bacterial and viral antigens is not clear. Some believe that the differences depend on an altered inflammatory tissue reaction in the

host which results in an unusual response to the antigen.

True allergic sensitivity must be differentiated from idiosyncrasy, in which the antigen-antibody mechanism is not involved. Idiosyncrasy simply represents a peculiarity in tolerance for a certain substance. In such cases one is unable to demonstrate circulating antibodies or skin reactivity.

Contact dermatitis, which plays an important role in allergic eczema, more so in adults than in infants, must also be differentiated from true allergy. It is an idiosyncrasy of the skin to contact with an irritating agent. Some agents produce dermatitis when they come into contact with any skin; others produce dermatitis only in peculiarly sensitive persons. The child with allergic eczema often acquires contact dermatitis from chemicals which would not otherwise irritate his skin.

#### *PATHOGENESIS OF THE ALLERGIC STATE*

Probably the most important factor in the development of clinical allergy is the inherited capacity to be sensitized allergically to foreign substances. It is estimated that about 75 per cent of allergic persons have a family history of allergy; about 35 per cent have a bilateral family history. In the latter instance the tendency in the offspring to allergy is greater, and the manifestations usually occur earlier in life and are more severe. The inherited quality in allergy is not a specific form of sensitivity to a specific substance, but simply the ability to develop an allergic type of sensitization. The mother may be sensitive to one food, the child to another. The types of reaction may also be dissimilar; for example, the mother may have hay fever and the child eczema.

Both allergic and nonallergic persons may become sensitized (develop specific antibodies after ingestion of a particular food) and yet not have clinically manifest disease. Not infrequently persons with a positive family history of allergy will react on skin testing to pollen of ragweed or other plants, yet show no symptoms when these pollens abound in the atmosphere. Many known and probably many unknown factors may help to explain such phenomena. Factors related to age limit the allergic response; the frequency of eczema in infancy and the rarity of asthma in the very young infant illustrate an age difference. Often the occurrence of an acute infection in the allergic person is the trigger for an asthmatic attack. Peshkin found that asthma frequently had its onset shortly after pertussis

and sometimes after measles. The part played by such infections is not clear. Some have felt that they are related to bacterial sensitization, others that the alteration of the immune state by the infection is more important; for example, the response to an injected antigen increased during tuberculous infection in animals.

Reactions to specific foods which occur only during the pollen season suggest synergistic actions of antigens. There is evidence that combined administration of a strong antigen with a weak antigen increases the antibody response to the weak antigen.

Alterations in hormonal balance influence clinical allergy as evidenced by changes in allergic reactivity during pregnancy and the profound effects of corticosteroids in depressing both antibody production and the allergic response itself.

Dehydration depresses the allergic response, which varies also with changes in the salt composition of the body. Little is known of the mechanism by which the allergic response is thus altered. The reaction of the dehydrated animal to intravenous histamine is depressed, suggesting an altered neuromuscular response.

Sensitization in the fetus may occur by the passage of preformed antibodies across the placenta, but permanent sensitization does not develop in this manner.

Active sensitization can be induced by placental transfer or by ingestion of antigens in breast milk, as evidenced by the fact that many infants with atopic eczema are sensitive to egg white before eggs have been eaten. The removal of a particular food from the mother's diet has relieved eczema in a nursing infant. Whether cows excrete foreign antigens (such as those of grass, weeds or grains) into their milk is not known. Since overindulgence in certain foods, especially uncommon ones, floods the circulation with antigen (in nonallergic as well as in allergic persons), it might be wise for the pregnant or nursing woman in families known to be allergic to refrain from overindulgence in an effort to spare the child this specific sensitization.

The normal adult may absorb unsplit proteins from his gastrointestinal tract, and there is evidence that this tendency is even greater in the young infant. Schloss showed that when a new food is introduced into an infant's diet, antibodies against it are produced which indicate absorption of whole protein; subsequent administration of the food is not

followed by further antibody responses. With each new food this process is repeated. With the rapidly expanding diet during infancy many occasions arise which induce new antibodies, and which in the allergic child might well induce clinical allergy. Consequently it would seem good practice to continue breast feeding for several months in infants of allergic families. The feeding of cow's milk while awaiting the arrival of breast milk in the early days of life may be a dangerous practice for such babies.

Food mixtures are not advisable for the allergic child, since they create confusion in planning elimination diets. Owing to the possibility of sensitization induced in utero or through breast milk and because the intensity of the allergic reaction varies directly with the amount of antigen consumed (after original sensitization), it would seem prudent to begin each new food cautiously. When sensitization to a particular food is not great, cooking may change the antigenic constitution of the food sufficiently to allow its ingestion without inducing an allergic response, as in the case of milk or egg.

Sensitization also occurs by inhalation, absorption through the skin and by parenteral injections of foreign substances.

#### **METHODS OF TESTING FOR HYPERSENSITIVENESS**

**History.** An adequate and detailed history is the most reliable tool for detection of the antigen producing an allergic manifestation. It must be remembered that three to four weeks may elapse between the ingestion of a new food and the clinical manifestation of allergy to it. This interval may be greatly shortened in persons who may be more active antibody producers or are more alert reactors. In a child sensitized in utero or through breast milk an allergic response may occur within a few moments after the ingestion of a new food.

**Elimination Procedures.** Elimination of potential allergens is an effective method for detecting the etiologic agent in the young infant whose diet is composed of few foods and whose environmental contacts are relatively limited. The mother who undertakes such elimination must understand the completeness with which selected foods must be eliminated as well as the need for accurate observation. Early and minor changes in the child's disposition, which can usually be detected only by the mother, may provide the clue to the causative agent.

Foods are the main cause of allergic reactions in children under two years of age. Inhalant allergens play a relatively minor role in infants, although allergic rhinitis during the second year of life is not uncommon, and eczema due to the inhalation of house dust is thought to occur after infancy. About four to five years of age the incidence of allergic reactions to foods and inhalants is about equal. After this age inhalants become the more common etiologic factor, although foods remain an important consideration throughout life.

The foods most commonly allergenic for the young child are cow's milk, egg, wheat and orange. Hill found that many infants who had positive skin reactions to lactalbumin also reacted to casein. Since casein is antigenically similar in all species, in these instances there would be no therapeutic value in changing from one milk to another. Cross reactions may also occur with lactalbumin.

The elimination diet in the infant may be limited to milk and crystalline vitamins. If it is advisable, the antigenicity of whole cow's milk may be decreased by boiling for fifteen to twenty minutes or by acidification with lactic acid, or evaporated milk may be substituted. Since milk with additional vitamins is almost a complete diet, the child may be maintained on it for some time without fear of nutritional deficiency. If the offending substance is absent in this diet, improvement should be noted within five to seven days in the case of eczema or other persistent allergic phenomena. New foods can be added one by one at weekly intervals, starting with small quantities if the child is closely observed for changes in the clinical disease.

If no improvement is noted when cow's milk is the sole food, some other milk, human or goat, or, better still, some nonmilk product such as soybean "milk," amino acid "milk" or meat "milk" may be given.

In older children, who have a more complicated diet, the elimination diets of Rowe (p. 1412) may be used to advantage.

Rowe suggests four diets: one of them consists of milk alone; another excludes the three most common offenders, milk, egg and wheat; the other two are composed of foods that rarely cause sensitization. A diet should be given for ten days before changing or making additions to it. In the case of eczema, all possible contact irritants should be removed while the diet is being investigated. In the case of asthma, inhalant allergens should be eliminated when possible; the

child's bedroom and playroom must be cleared of such common inhalants as feathers, wool particles, house dust and animal danders. An air conditioner in the room may help in eliminating pollen.

To eliminate all contact and inhalant allergens, it may be necessary to place the child in a clean, bare hospital room where the environment is more readily controlled. Tolerance tests for environmental factors may be begun in the hospital after clinical manifestations have subsided.

The best test for the clinical importance of a potential allergen is administration of it by the route it is normally taken. If the asthmatic episodes are believed to result from contact with a cat, for example, skin testing with cat dander is not so reliable a test as having the child play with a cat. In a highly sensitive child exposure to known excitants may be dangerous, and these tests should, therefore, be done with great care.

**Skin Tests.** When it is impossible to identify all offending allergens by history or elimination regimens, specific testing of the reactivity of skin or mucous membrane can be done. Complete reliance, however, cannot be placed on skin testing for determination of the causative factors in allergic disease. As noted elsewhere, positive skin tests to specific substances may be obtained in the absence of any evident disturbance when the person is exposed to them. On the other hand, a high percentage of foods which produce gastrointestinal symptoms when ingested do not incite positive skin tests. Under certain circumstances, moreover, as during dehydration states or fever or after an acute allergic episode, the skin reactivity to an antigen may be depressed temporarily, as it is, for example, to tuberculin. The skin of the very young infant reacts relatively poorly to skin tests, and, since he is a poor antibody producer, the passive transfer test is of little value.

Before using any testing material it is important that its potency be known. This can be done only by testing persons known to be sensitive to the materials. Reliable antigens for testing are supplied by many commercial firms. Certain extracts are nonspecifically irritating and produce falsely positive reactions.

**Intracutaneous test.** The intracutaneous test is the most reliable of skin testing methods, although falsely positive reactions are more common with it than with the others. It has the advantage of being easily quantitated, so that some estimate of the degree of sensitivity can be had. The initial intracutaneous test

should be made with a weak dilution of the extract. Only 0.01 cc. of solution should be injected, care being taken that it be placed intracutaneously. The height of positive reaction occurs within ten to fifteen minutes, at which time the test should be read. A reaction which develops pseudopodia is of the highest order of magnitude and may be recorded as 4 plus; positive reactions of a less degree can be graded downward to 1 plus. The estimation of the degree of reaction is arbitrary, and each physician must set his own standards. Since constitutional reactions are not uncommon, no test should be performed without epinephrine available for hypodermic administration, and a tourniquet at hand so that the circulation above the test site can be occluded to prevent further absorption in the case of reaction. For safety it is best to perform intracutaneous testing only if the scratch test is negative. In the case of eczematous children an intracutaneous test with egg white probably should not be done even though the scratch test is negative.

**Scratch test.** The scratch test is usually performed on the forearm or back. An aseptic superficial scratch is made about  $\frac{1}{8}$  inch in length with an attempt not to draw blood. Liquid antigens, such as sterile milk or egg white, or solid antigens dissolved in tenth-normal sodium hydroxide or prepared as liquid glycerin extracts, are dropped on the scratch and gently rubbed into it with a fresh wooden or glass applicator for each antigen. The test is read in fifteen to twenty minutes. The sodium hydroxide solution should be used as a control test.

**Patch test.** The patch test is useful for contact antigens, but is often difficult to evaluate. The antigen tested may cause dermatitis only under certain circumstances, as in the presence of moisture or friction or at a certain pH, or the reaction may be limited to the areas of allergic dermatitis. To evaluate the test properly, one or more of these conditions may have to be reliably reproduced, and some knowledge of the nonspecific irritating qualities of the test substance must be had. The testing patches are prepared by placing the antigen in powder or liquid form on a small piece of filter paper, centered on a square of cellophane which in turn is placed on a larger square of adhesive. In the usual case the coverings are removed in forty-eight hours and the test read. If itching develops, the coverings are removed and the test material washed off. In the case of irritating oleoresins the test may be read after one hour.

**Mucous membrane tests.** The ophthalmic test for sensitivity to serums and direct testing of the nasal mucous membrane with inhalants are at times valuable aids. When the skin test is positive to a therapeutic serum, the instillation of 1 drop of a 1:10 dilution of the serum into the conjunctival sac may determine whether or not it is safe to give the serum. A positive conjunctival test is evidenced by chemosis of the eye and tearing. When the skin test is positive and the eye test is negative, the chances of a dangerous reaction following serum administration are remote. If both tests are positive, serum of another species should be sought. Severe chemosis of the eye can be alleviated by instillation of 1 or 2 drops of a 1:1000 solution of epinephrine. By applying the antigens of inhalants to the nasal mucous membrane one can determine whether a positive skin test

is diagnostic. If no reaction occurs when the pollen is directly applied to the nose, it is unlikely that this pollen is the cause of the symptoms. These tests should not be applied during the pollen season.

**Passive transfer test.** The passive transfer antibody found in the blood plasma is the characteristic antibody produced in the allergic person and can be used to sensitize the skin of a nonallergic person to a specific antigen. This is the *Prausnitz-Küstner reaction*. This test is of little or no value when antibody production is low, as in the very young infant. It has its greatest value in testing an eczematous infant whose entire skin area is involved or in infants with dermographism who respond to every trauma with false reactions. It is also of value in checking a positive direct skin test reaction. Since direct testing is usually more informative, it is reasonable to delay testing until the skin is treated and the child can be tested directly.

The skin of a healthy nonallergic person is prepared for the passive transfer test by injection of 0.05 cc. of the patient's serum intracutaneously in each of a series of areas on the volar surface of the forearms. Care should be taken that the serum is sterile, that it is Wassermann negative and does not contain malarial or other parasites. A history of hepatitis in the patient should preclude its use. The areas injected are ringed with gentian violet in a circle about 1½ inches in diameter to denote the area sensitized. Twenty-four to forty-eight hours are allowed to elapse before subsequent testing with the suspected antigens, so that adequate localized cellular sensitization may develop. These areas remain sensitized for four to five weeks.

Tests are performed by intracutaneous injection of the suspected antigens; a control test with each antigen is made on unsensitized skin of the recipient just opposite the test area. An appreciable increase in degree of response of the test area over the control indicates a positive reaction. Sites where positive reactions have occurred should not be used for further tests. Areas having negative responses may be used over again. The recipient should not eat the foods to be tested within twenty-four hours before the tests are performed, for if the testing serum is of high titer, the sites may react to them.

### Selection and Interpretation of Tests.

The choice of reagents for testing will be guided by the probable nature of offending substances as indicated by a carefully taken history, which should explore in detail the relationships of onset or disappearance of allergic symptoms to changes in diet or environment. It is impracticable and inadvisable to test the allergic child with all available antigens when in many cases a dozen or so well chosen tests will detect all major offenders.

In infants with eczema or gastrointestinal allergy particular attention should be given to testing those foods known to be part of the diet. In the case of mixed foods in the diet it will be necessary to appraise each constituent, but it is generally better to eliminate

such foods entirely than to test to all possible allergens therein. Gastrointestinal disturbances have been associated with ingestion of certain canned foods which did not occur with the same food prepared at home. House dust and wool, common offenders in eczema, should also be considered for testing.

In inhalant allergy the detailed composition of articles of furniture (chairs, bed rugs, pillows, mattresses, draperies), toys and clothing should be established and possible offenders tested. House dust, feathers, wool, seasonal allergens (pollens, molds) and animal danders should receive attention as indicated; these allergens may induce atopic dermatitis as well as respiratory manifestations through inhalation. Occasionally dyes and other synthetic materials in garments require careful study.

It is advisable that only two or three tests be done at the initial visit. This allows an estimate of the reactivity of the skin and of the general hypersensitivity of the patient so that severe constitutional reactions can be avoided. One should not include in the first group of tests more than one of the substances which from the history are possible offending agents, since a cumulative effect might result in a constitutional reaction. Furthermore, if all tests are positive, one cannot be certain whether they are true positive reactions or whether they result from nonspecific irritation of a reactive skin. When great numbers of tests are positive, they should be checked by passive transfer testing. The child should be watched for at least a half hour after testing, since constitutional reactions may be delayed.

A positive skin test reliably performed when the antigen itself is not irritating denotes allergic sensitivity to the material tested. It does not indicate that the allergic disease present is necessarily caused by the reacting substance. It may represent a past etiologic factor no longer involved or possibly a future excitant. In order to incriminate the positively reacting substance as a causative factor in the disease, the specific antigen must be demonstrated in the child's diet or environment. It would be reassuring if its withdrawal were always associated with relief from symptoms and its reincorporation would again produce the disturbance. Owing to the frequency of multiple sensitivities, however, the removal of a single offending substance is often not followed by relief.

The highest percentage of positive skin reactions occurs in hay fever and pollen

asthma patients, in more than 90 per cent of whom hypersensitivity can be demonstrated. In children with other forms of asthma and with eczema, positive reactions occur in about 75 per cent. Only about half of the patients with gastrointestinal allergic symptoms and fewer of those with urticaria and angio-neurotic edema react positively.

Before an essential food substance is eliminated from a child's diet because of a positive reaction, the skin test with the specific antigen should be repeated so that the presence of a positive reaction is verified. *Good clinical judgment rather than blind reliance on skin testing will benefit the patient most.*

#### TREATMENT OF THE ALLERGIC STATE

Since there is no means to eliminate the inherited quality which makes the patient atopically hypersensitive, treatment of an allergic condition is limited to (1) removal of offending allergens, (2) hyposensitization against specific allergens, and (3) decreasing the responsiveness of the child toward offending allergens.

**Removal of Offending Allergens.** At times, when a single or only a few allergens cause symptoms, excellent results are obtained by their avoidance. Too often poor results are due to the mother's lack of understanding of the thoroughness with which elimination must be effected. Bread or crackers may contain enough milk to continue a "milk disturbance," and other prepared foods may contain such common allergens as egg and wheat. Lanolin may be thoughtlessly used in wool sensitivity. Time must be taken to explain all possible sources of trouble.

Sensitivity to specific foods is often not permanent. Sensitivity to milk in the infant, for instance, may disappear after a few months. Even hypersensitivity itself may be completely lost. For this reason, after a period of elimination of several months, one may cautiously reinsert the allergen into the diet or environment. This should be done only if continued avoidance imposes unusual hardship or if the former allergen is felt to be essential. Such a test should be made with great care, since reintroduction of the allergen may be followed by an explosive allergic episode.

At times the clinical expression of allergy is mild; if the causative agent is an important food, as, for instance, milk, one must weigh harm against good in determining whether to remove the offending substance. Thus in mild eczema it may be elected not to alter the diet,

but to use local treatment only. The diet of the child must remain nutritionally adequate. The Rowe elimination diets (p. 1412) are especially useful for older children.

The removal of offending pollen allergens can be accomplished by sending the patient to a pollen-free locality or by air-conditioning his room. Freedom from pollen inhalations for the long night period often results in day-long relief.

The antigenicity of certain foods can be decreased by various procedures, for example, that of milk by prolonged cooking, acidification, evaporation and drying.

**Hyposensitization against Known Specific Antigens (Desensitization).** In the case of multiple sensitivities or when the exciting antigen or antigens cannot be determined or the allergen cannot be avoided (house dust, pollens, molds), measures aimed at decreasing the responsiveness of the child to the allergen may prove helpful. Specific hyposensitization is used mainly in the treatment of pollen sensitization. When such essential infant foods as milk or egg are found to be the cause of an allergic disturbance, they can be given orally in minute and gradually increasing amounts to bring about hyposensitization. In eczema it is best to remove all egg from the diet. Hyposensitization with vaccines (antigen) made from bacteria isolated from the patient's upper respiratory tract occasionally proves helpful.

Treatment by hyposensitization is based on the assumption that the injection of small quantities of antigen in gradually increasing doses increases the circulating antibodies. Decrease in symptoms is associated with a reduced dermal and conjunctival response to the antigen, but the existence of a high level of antibodies accounts for persistence of some degree of skin sensitivity.

The rapid return of clinical hypersensitivity when antigen injections are discontinued results from a fall in circulating antibodies. There is a limited capacity for antibody production, which, when attained, cannot be raised by continued injection of antigen. The ceiling of antibody production following the injection of pollen antigens as well as some others is reached more rapidly in subsequent courses of treatment and with smaller doses of antigen than during the first course. However, except in rare instances and in older people, who tend to lose their atopic manifestations, the cessation of specific therapy is followed by return of symptoms.

Temporary insensitivity to antigens follows

sublethal anaphylactic shock in sensitized animals; this is not a safe procedure in man.

Before hyposensitization is undertaken it must be decided whether the severity of symptoms justifies treatment. When the symptoms are mild and infrequent, they may be better tolerated by the child than a series of painful injections. It is possible, however, that later development of asthma and asthmatic bronchitis may be prevented by early treatment of mild respiratory allergy.

Only with certain proteins and in certain persons is complete relief of symptoms possible. Subcutaneous injections of pollen antigens result in complete relief in only about 20 per cent of the cases, although the majority of patients have their symptoms reduced by about 75 per cent; some are made ill by each injection.

In hyposensitization by the subcutaneous method the initial dose is determined by the degree of skin reactivity and should contain the smallest amount of antigen which produces a positive intradermal test. There is wide latitude in choosing the subsequent doses, the interval between doses, and how long to carry on treatment. The largest dose is usually about 500 to 1000 times the initial dose, with each dose one and a half times to twice the preceding doses (somewhat less at high dosage levels), with an interval of three to five days between injections. If severe reactions occur, the preceding dose may be repeated and subsequent doses increased at a slower rate. Patients with a high degree of sensitivity will secure relief with smaller doses of antigen than those less sensitive.

In *preseasonal therapy* for pollen asthma or hay fever it is desired to attain the maximum dose just before the onset of the pollen season. In the usual case this will require about three months when the weaker dilutions are given at three-day intervals or the stronger ones at five-day intervals. Since the injected pollen remains antigenic for forty-eight to seventy-two hours, the interval between doses should not be less than three days. On the other hand, if the interval is too long, loss of hyposensitization may occur. Opinions differ as to whether treatment should be continued after the season has begun. When treatment is continued, the dose should be about half the maximum one and given at seven- to ten-day intervals.

When treatment is discontinued and when the pollen season is over, the degree of protection rapidly falls off. To maintain a high degree of hyposensitization after specific ther-

apy the person must remain more or less constantly in contact with the allergen. This is as true for foods as for pollens.

Many allergists recommend *perennial treatment* for pollen sensitization to avoid repetition of intensive preseasonal treatment. When the maximal dose is achieved in the initial preseasonal treatment, half of this dose is given at weekly intervals throughout the pollen season and then every three or four weeks throughout the year until four to six weeks before the onset of the next season. Then the interval is shortened to five days and the dosage gradually increased so that the original maximal dose is reached as the season commences. Some allergists give the maximal dose for perennial treatment and do not shorten the interval of treatments pre-seasonally.

When a patient with pollinosis has received no preseasonal treatment, *coseasonal therapy* may be tried. The results are not so good as with preseasonal therapy, but there is often some benefit. In coseasonal therapy small doses are given at short intervals with no attempt to attain large doses. The intracutaneous route of injection is preferred. Should relief occur after the first few daily injections of increasing concentrations of pollen, the dose is not increased further. The amount of antigen to be given is the amount necessary to produce a wheal about a centimeter in diameter.

Before any injection the patient or his parent should be asked whether a reaction occurred after the previous injection, so that the dose to be given can be properly adjusted. Severe constitutional reactions may appear immediately after the injection or be delayed for an hour or so. The immediate ones may be fatal. All foreign proteins are more safely given into an extremity than into the trunk, so that a tourniquet can be placed above the site of injection, if necessary, to slow the rate of absorption. Epinephrine (0.3 to 0.5 cc.) should also be given subcutaneously in the other arm for severe constitutional reactions, and an equivalent amount injected at the site of the reaction. When symptoms are delayed for an hour or more, they may be distressing, but are rarely serious; their management is similar to that of manifestations which occur soon after injection. In the milder cases the reaction is local with itching and swelling. Generalized urticaria and sneezing may be associated with moderately severe reactions, and asthma and anaphylactic shock with the serious ones.

FIG. 418. A summary diagram of the mechanism of the allergic response and the sites of action of the 3 modes of treatment, *a* = Antigen—Its removal from the environment eliminates the antigen-antibody reaction. *b* = Sensitized cell with attached antibody. Hyposensitization is presumably brought about by the production of an immune or blocking antibody which prevents the antigen from attaching itself to the antibody (reagin) on the sensitized cell. *c* = Liberation of histamine, serotonin and possibly other substances, normally within the cell, after cell injury induced by the antigen-antibody union. The action of the so-called antihistaminics (Pyribenzamine, Benadryl and others) in preventing the histamine effect is thought to be accomplished through competitive inhibition for sites affected by histamine. Epinephrine has its beneficial effect in opposing the pharmacologic action of histamine through stimulation of the sympathetics. *d* = The neuromuscular organ which is stimulated to produce the clinical reaction by the "H" substance. Many nonspecific measures reduce its responsiveness; ACTH and cortisone may play their major role in this capacity.

In most instances severe reactions can be prevented by attention to details in treatment. Care should be taken that the antigen is not injected intravenously. Successive doses should be increased cautiously. If a long interval has elapsed since the previous injection, the next dose should be reduced. When a patient has a reaction with each injection, the dose should be reduced or treatment discontinued entirely. The administration of epinephrine with each dose may delay the reaction, but usually does not prevent it; when epinephrine is given with pollen extract, it promotes permanent skin marks. Administration of an antihistaminic drug before injections of antigen may avert untoward reactions.

**Decreasing the Responsiveness toward Offending Allergens (Nonspecific Hyposensitization).** There is suggestive but inconclusive evidence that the allergic response

may be decreased by a variety of nonspecific means. In evaluating any therapy, however, the frequent fluctuations in severity of symptoms which occur in the natural course of allergic states must be kept in mind. Reference has been made to the alterations in allergic responsiveness which depend on age. During hormonal upheavals, such as occur in pregnancy, there may be favorable fluctuations in the allergic response. Estrogenic substances have been helpful during menopausal urticaria; occasionally thyroid medication has been of value in treating eczema in the hypothyroid child. The corticosteroids greatly decrease allergic responsiveness by mechanisms not clearly elucidated. Emotional outbursts are often followed by itching and flare-ups of eczema or bouts of asthma. Psychotherapy may justly be considered a method of inducing nonspecific hyposensitization.

Severe illness and states of dehydration often lead to a decrease not only in allergic symptoms, but also in skin reactivity to specific antigens. It is not uncommon for an eczematous eruption to disappear during a state of acute dehydration, only to reappear when the infant is again hydrated. Anaphylactic shock in the guinea pig can be prevented by dehydration brought about by water restriction, sodium chloride depletion or potassium chloride administration, whereas measures which favor retention of water, such as forced water feeding and sodium chloride administration, exaggerate the anaphylactic response.

Definite improvement has been observed in infants with eczema following use of measures promoting mild dehydration; older children with eczema have not responded as well. Asthma, hay fever and other forms of allergy also are often improved by this form of therapy. Care should be exercised to avoid such a severe state of dehydration as might impair kidney function or produce inspissation of bronchial secretions.

The so-called antihistaminic drugs are discussed with the individual allergic disturbances (see p. 1320).

Sedatives and antispasmodic and anesthetic drugs are sometimes helpful in allergy states. Nonspecific protein and vaccine therapy have been used with indifferent results. Though good results have been attributed to the use of vitamins, especially ascorbic acid, in large doses, clinical experience has not been confirmatory. When multiple factors are responsible for an allergic disturbance, the control of one or more of them often reduces the

allergic response to the others. This is strikingly demonstrated in the relief from allergic disturbances brought about by prevention or cure of respiratory infections. Resistance to allergic manifestations is increased by adequate rest, and the allergic response is minimized when the general health of the child is at its best.

## ECZEMA

The term "eczema" is used for a wide variety of unrelated inflammatory dermatoses. In adults contact dermatitis is commonly regarded as eczema, whereas, in childhood, eczema is considered an atopic manifestation to some specific allergen which is usually ingested, but may be effective by contact. Eczema is the most frequent expression of the allergic state in the first year of life. Few diseases in infancy produce so much annoyance to baby, mother and physician. The clinical manifestations in the infant differ from those in the older child. Frequently

eczema in the infant is complicated by contact dermatitis resulting from an applied medication, or true allergic contact dermatitis, as to silk or wool, which may be the primary entity. Seborrhea is uncommon in the older child, but is frequently associated with infantile eczema and may be mistaken for it.

## INFANTILE ECZEMA

### (ATOPIC DERMATITIS)

Eczema is commonest during the first two years of life, commences often during the first few months and occurs most frequently in bottle-fed babies or in breast-fed babies who receive additional foods. It is occasionally seen in wholly breast-fed infants as a result of passage of food proteins through the breast milk. An infant, of course, can be sensitized by antigens through inhalation or by contact. There is no predisposition according to sex or race. It occurs most frequently in the winter months.

**Etiology.** In spite of general agreement on the allergic quality of infantile eczema, it is not always possible to demonstrate specific hypersensitivity by skin tests or passive transfer. This fact has led to differences in opinion concerning the underlying mechanism, many doubting that an antigen-antibody mechanism is involved. The high incidence in later years, however, of hay fever and asthma in children who had eczema in infancy favors an allergic basis. It is presumed that about 75 per cent of the cases of eczema in infants and children is atopic dermatitis.

The importance of local skin factors in infantile eczema is uncertain. The skin of the infant differs from that of the adult anatomically and chemically and shows greater inflammatory response to scratch (dermatographia) and to other irritants. Changes in skin reactivity with age may account for the different character of eczema in the older child (neurodermatitis) and for the loss of the tendency to exhibit eczema as a manifestation of allergy. Such normal characteristics of the infantile skin as increased irritability and high water and sodium chloride content are said to be exaggerated in the skin of eczematous infants. Moreover, improvement may result from protection of the skin from irritation and from measures designed to reduce the water and the sodium content of the body.

Possible sources of irritation include rubbing or scratching and irritation from clothes, foam soaps, hard water, cold, wind and strong

sunlight, or skin infection. These may be important factors in the continued activity of infantile eczema.

Infection in the skin is of great importance in determining the degree of activity of some cases of infantile eczema. Even without pustulation large numbers of bacteria, chiefly streptococci and staphylococci, may be found. Rapid improvement may occur at times with antimicrobial therapy. Flare-ups of eczema often occur with infection of the respiratory tract.

The significance of unsaturated fatty acids in eczema is not clear. The level of them in serum may be low in infantile eczema, but in our experience the feeding of unsaturated fatty acids in linseed oil has not resulted in striking benefit (p. 102).

Overfeeding may have an adverse effect in eczema. Fat infants tend to have a moist, weeping eczema; thin ones a dry, scaling eczema. Feeding of large amounts of carbohydrate tends to increase water retention. Reduction in the carbohydrate intake often leads to improvement in the skin. Reduction in the fat of the diet has also been said to improve the condition of some patients (see above). Hill postulates that sensitivity to egg white, commonly found in the eczematous child, is in some unknown way important in the etiology of the disease.

**Clinical Manifestations.** The lesion in infantile eczema is characterized by papulation and vesicle formation, individual lesions at a given time often being in various stages of development. The vesicles rupture and exude a sticky, yellowish material which dries to form crusts. Scratching leads to the characteristic punctiform and excoriated appearance. When the crusts are removed, there is often bleeding from an inflamed moist surface. Milder lesions are less moist and inflamed, and scaling is frequently present, which may be a manifestation of an associated seborrhea. Severe and mild lesions may coexist in different parts of the body, and relatively inactive lesions may suddenly become acutely inflammatory. Thickening of the skin, formation of fissures and secondary infection with pustulation often follow scratching. Itching may be intense.

Infantile eczema occurs characteristically on the cheeks, forehead and scalp; occasionally behind the ears, on the neck and on the flexor surfaces of arms and legs. At first the skin is red and edematous, and when the swelling is extensive on the head and face, the appearance of the child may be greatly

distorted. Lesions on the trunk, abdomen and back tend to be drier and more circumscribed than elsewhere and are associated with more scaling. The entire body except the palms and soles may be involved. Occasionally a diaper dermatitis accentuates or localizes the eczematous eruption to this area.

In severe eczema infants are made uncomfortable and irritable by constant and intense itching, and loss of sleep may become serious. Affected infants are ingenious in their ability to rub and scratch itching parts despite restraining devices. Low grade fever may exist in the presence of superimposed bacterial infection. The regional lymph nodes become enlarged, but rarely suppurate. Splenomegaly is frequent. Most eczematous infants are overweight, but malnutrition may be present as a reflection of anorexia, chronic infection, persistent or recurrent diarrhea or dietary restriction.

Mild infantile eczema may be notably capricious. Many infants with an atopic family history have a mild eczematous rash only intermittently. Though these infants, like those with more persistent eczema, may subsequently have asthma, there is usually no necessity for restriction in the diet.

Flare-ups of eczematous lesions may follow prophylactic immunizations. The occasional development of generalized vaccinia in infants or children with eczema argues for deferment of smallpox vaccination unless there is a high probability of contact with the disease. Generalized vaccinia in eczematous infants may also occur from contact with a sibling or another child recently vaccinated, and such contacts should be scrupulously avoided. Kaposi's varicelliform eruption may result from superimposed herpes simplex on the eczematous lesion.

*Eczema in the older child*, whether or not previously present in early life, is similar to eczema in the adult, being characterized chiefly by thickening and lichenification. The lesions are usually symmetrically located in the flexures of the knees and elbows, about the wrists or on the back of the neck and ears. Scaling is frequent. Small, circumscribed, thickened, reddened, scaly patches may occur on the chest or back. The lesion is chronic, but acute exacerbations are common. Itching is intense, and infection and mechanical irritation from scratching play a large part in modifying the lesion. Dermato-graphia is not so prominent as in the infantile form of eczema.

So-called nummular eczema occurs in older

FIG. 419. Infantile eczema.

infants and children as localized patches originally composed of small vesicles and later becoming dry and crusting. They are scattered over the trunk and the extremities and may be associated with characteristic atopic eczema elsewhere on the trunk. The lesions tend to recur at the sites of first appearance. Localized infection in the skin is thought to have some etiologic significance. Hill maintains that removal of environmental allergens and foods is not helpful in this form of eczema unless it is associated with typical atopic eczema.

**Differential Diagnosis.** The diagnosis of infantile eczema is based on the characteristic eruption about the face and head, the itching, family history of atopy, eosinophilia and the demonstration in most cases of protein sensitivity.

*Seborrhea* does not have the characteristic vesiculation of eczema; the lesion is dry, and the scales are yellow and greasy. There is little itching, but severe inflammation and moisture may be present. The distribution may be patchy, as in dry eczema, but it often begins as "cradle-cap." When seborrhea is the sole manifestation, the differentiation is clear. The disturbance is not so persistent as eczema and yields readily to salicylic acid ointments. The two diseases may occur together, seborrhea usually preceding the atopic eczema.

*Leiner's disease* (p. 1284) is regarded by

many as a severe form of seborrheic dermatitis and has the essential characteristics of that disease. *Papular urticaria* has more distinct papules with little or no vesiculation and is found most frequently on the extensor surfaces of the arms and legs. *Scabies*, when complicated by scratching, may present some difficulties in diagnosis. It rarely involves the face, except in the breast-fed infant, and commonly is present in other members of the household. The characteristic burrow can usually be discovered. *Diaper dermatitis* can be excluded by a rapid response to treatment (p. 1298). *Papular eczema* involving the buttocks may resemble *congenital syphilis*, which must be excluded by appropriate tests. *Moniliasis* in very young infants with lesions particularly in the diaper area must be differentiated. Some of these infants have had oral thrush in the newborn period. Skin cultures will aid in the diagnosis. *Eczematoid eruptions* secondary to chronic skin infection and to purulent draining ears and sinuses must also be differentiated.

**Treatment.** The results of treatment in severe eczema may be far from satisfactory, but most patients can be significantly helped by therapy. Success will depend in large degree upon the mother's understanding of the disease. She will need to know that infantile eczema has exacerbations and remissions and that it may be discouraging from time to time. Infantile eczema will ultimately

disappear spontaneously in most instances, usually by the second or third year of life.

Whenever possible, the infant with eczema should be treated at home. In severe eczema, however, especially when secondarily infected or when mother and child are both exhausted, care in the hospital may become necessary. Strict isolation of the infant to prevent cross infection is necessary for his own protection and for that of others.

The treatment of infantile eczema can be considered in three categories: local, specific and nonspecific.

**Local treatment.** This is the most important factor in the treatment of eczema. Scratching and rubbing, which will encourage inflammatory activity, must be prevented. Scratching can largely be prevented by placing heavy cardboard cuffs about the elbows. The fingernails should be cut close and kept clean to prevent infection. The hands may be encased in cotton stockings. Heavy cellophane sheeting placed under the infant will prevent rubbing on the bedding. When the eczema is extensive, moist or infected, the clothing is best removed and the child placed under a heat tent to prevent chilling. Otherwise a light cotton diaper and loosely fitting cotton nightgown may be worn. Overdressing and too warm bed coverings aggravate the disease by inducing sweating.

No woolen garment should come in contact with the skin of an eczematous infant.

The infant can be bathed if water does not irritate his skin; mineral oil can be used for tender, inflamed areas. A mild soap may be used for cleansing. If it produces irritation, a soap substitute can be used. A hexachlorophene product, such as pHisohex, is particularly helpful in the presence of infection.

Ointments and lotions are the most important elements of local treatment. Different types of lesions may occur on various parts of the body at the same time and require different types of care. Ointments should not be used when there is weeping. When there is induration, the ointment should be gently but thoroughly rubbed in. The ointment or lotion should be kept constantly on the skin, regardless of the frequency of application.

Associated seborrheic dermatitis of the scalp can be controlled by application of 1 or 2 per cent salicylic acid ointment under a thin cotton cap. This procedure is continued for three to five days, no attempt being made to cleanse the scalp between the daily applications of the ointment. On the final

day a thorough shampooing with castile soap or pHiso-hex and water will usually clear the scalp. Occasionally the treatment may need to be repeated.

It is difficult to keep medication applied to the face. When a thick mass of scabs and crusts covers the surface, it is removed as much as possible by gentle wiping with gauze saturated with liquid petrolatum. Saline soaks, kept continuously wet for a day or two, are also helpful in removing encrustations. A facial mask of gauze is easily prepared.

During the acute inflammatory phase of the eczema, infection of the skin seriously affects the course of the disease. If there is not too much oozing, an ointment containing bacitracin or bacitracin with neomycin may be effective in controlling the infection. Some clinicians prefer an antibiotic lotion for this stage and feel that there is less danger of sensitization than with an ointment. Antipruritics in the form of menthol, phenol or chlorobutanol (Chlorotone) may be added to the ointment or solution. In the presence of severe infection systemic antibiotic therapy is indicated; because of the lesser chance of sensitization, it is actually preferable to local therapy in all instances. If, after the crusts have been removed, a wet oozing surface remains, a mild astringent lotion should be applied to dry the surface before applying tar ointment. One of the following lotions may be sponged on frequently for two or three days:

	Gm. or ml.
Burow's solution.....	16.0
Water.....	240.0
or	
Potassium permanganate.....	0.4
Water.....	120.0

1 teaspoonful of this solution to 1 quart of water gives about a 1:10,000 dilution of permanganate.

A 3 per cent Burow's solution containing 200 mg. of neomycin to 8 ounces of solution is recommended by Osborne for this purpose.

When the surface is dry, red and papular, an ointment containing tar, such as the following, is most effective:

	Gm.
Crude coal tar.....	3.0
Zinc oxide.....	5.0
Starch.....	50.0
Petrolatum, to make.....	100.0

The tar and the zinc oxide are combined, the starch is incorporated in the petrolatum, and the 2 mixtures then combined.

If the area is highly inflamed, Lassar's paste can be used as a protective coat before applying tar.

Coal tar ointment should be applied as often as necessary to keep the skin covered. Some patients find coal tar unusually irritating, and in this case the concentration of the tar should be reduced one half. Tar should not be used where there is pustulation. When the eczematous lesions are dry, thickened and localized in small patches, crude coal tar may be applied twice a day and dusted over with talcum powder. A satisfactory ointment is 5 to 8 per cent liquor carbonis detergens in a vanishing cream base. One to 3 per cent crude coal tar in Lassar's paste may also be useful. A number of proprietary tar ointments, both black and white, are available and are often less messy than compounded ones. A small area should be tried initially to determine the degree of sensitivity to tar. Overtreatment may produce a wrinkled and drawn appearance of the skin and fresh papulation. Tar contains phenol, and for this reason not more than one fourth of the body surface should be covered at one time. Exposure of the parts covered with tar to direct sunlight should also be avoided, since tar is a photosensitizer. The areas of eczema on the trunk and extremities should be kept constantly bandaged and uncovered only to apply fresh ointment.

Each day before applying fresh tar ointment the old should be carefully removed with liquid petrolatum.

The ointment should be kept carefully sealed in jars to prevent evaporation of the volatile ingredients. Tar may be removed from linens by rubbing both sides of the material with lard, then washing with soap and water.

If large areas of the body are covered with papulovesicles, a starch bath before the daily application of an ointment may be useful.

When much of the infiltration, papulation and itching have disappeared, the tar ointment is discontinued and a milder one is applied; petrolatum or a simple zinc oxide paste may be useful.

Hydrocortisone ointment (1 or 2.5 per cent) containing an antibiotic is useful for the inflamed, scaly, rather superficial lesions. It should be applied twice daily and rubbed in gently. When the eczema clears, the therapy should be discontinued and resumed if the lesions return.

Small oozing cracks behind the ears may

be painted with plain crude coal tar. If they are wet, a neomycin-Burow's solution lotion may be applied until the moisture has disappeared.

Mild eczematous lesions, consisting only in patchy redness with a slight thickening and scaling, require little treatment. All sources of irritation such as soaps, water and rough clothing should be avoided. The involved areas should be cleansed with petrolatum or a detergent solution or ointment and a mild tar ointment as liquid carbonis detergens applied.

The local treatment of chronic eczema (neurodermatitis) in older children may be even more difficult than that of the infantile form. There is a tendency to recurrence, and itching is intense. Control of scratching is important, but complete restraint of the older child is not feasible, and partial restraints are unsatisfactory. Crude coal tar ointments are helpful. They must be vigorously rubbed in and then covered with cotton bandages. When the legs are involved, cotton overalls or long stockings help in the control of scratching. Treatment should be continued for some time after the lesion has cleared. If infection is present, antibacterial therapy may be indicated. Roentgen treatment is said to be helpful in chronic cases, but beneficial results may be only temporary, and the dangers of treatment are considerable.

Antihistaminic drugs have not been of great benefit in eczema. The itching may be ameliorated to some extent. Oral therapy is probably preferable to local use, since there is less likelihood of sensitivity developing.

**Specific treatment.** The specific treatment of eczema involves detection of the specific allergens, followed by their removal from the diet or environment or by hyposensitization (see p. 1309). Attention is first directed toward foods as possible allergens, but it should be remembered that contact with wool and with dust and other inhalants may also be causative factors.

In the infant whose diet is limited, elimination diets are the most helpful method of testing (p. 1412). Skin testing is not very helpful in infants for reasons previously noted, though it may be of considerable help in older children. If the offending foods are eliminated and adequate local treatment has been instituted, improvement should be apparent within a week or less. New foods may then be added in small amounts at weekly intervals.

If skin testing is to be carried out, it may

be necessary to use the passive transfer method (p. 1308) in the infant because of dermographism or extensive eczema.

If the eczema is mild, the diet may not need to be altered and treatment may be limited to local measures. Even in mild cases, however, the removal of orange juice should be tried.

Breast-fed infants with eczema should not be weaned except when an item in the mother's diet which cannot be removed is responsible. An elimination diet for the baby consists in restricting intake to breast milk, for the mother in the avoidance of likely allergens or, if indicated, a rigid elimination diet.

Wool should be removed from the immediate environment of the child. Every effort should also be made to eliminate sources of house dust and other inhalants which may be causative. Hyposensitization with house dust may also be tried when the skin test to this substance is positive. Hill recommends smaller doses of the antigen than those used for allergic rhinitis.

**Nonspecific treatment.** Nonspecific measures in the treatment of eczema have been discussed (p. 1311). Measures promoting mild dehydration are particularly helpful in the management of eczema and should be used in association with local and specific measures. In infants it is difficult to reduce the fluid intake without reducing the caloric intake, since many drink little or no water. A lower sodium intake may decrease the tendency to water retention. In debilitated infants, however, dehydrating measures must be avoided.

In stubborn, diffuse eczema corticosteroids may be used systemically as well as locally as previously mentioned. Hormonal therapy should not replace other sound therapeutic measures.

The treatment of skin infection or infection elsewhere in the body with an appropriate orally or parenterally administered antibiotic is an essential part of therapy.

#### ATOPIC ERYTHRODERMA

Some highly allergic infants have a diffuse form of eczema which often leaves the palms and soles as the only areas of skin free of involvement. The presence of a large element of seborrhea in the rash separates this particular form of infantile eczema from the more usual variety. The skin is red, thickened, fissured and scaly. There are varying degrees of edema of the skin and subcutane-

ous tissues during the acute phase and during exacerbations. The vesiculation characteristic of infantile eczema is rarely present. The scaling and thickening of the skin which are striking features of seborrheic dermatitis dominate the picture and produce a strong resemblance to Leiner's disease. In the acute stage the feet and hands are usually cold and bluish. Itching is intense, and much traumatic irritation may result if the child is not properly restrained. General lymphadenopathy is commonly present.

These children are sick: there is loss of appetite, undernutrition and often diarrhea. Irritability may be great, and there may be fatigue from loss of sleep. Eosinophilia and the presence of passive transfer antibodies in the circulation attest the atopic nature of the illness. Passive transfer antibodies against milk, egg, feathers and dust are commonly found.

The course is chronic. Rarely does the eruption clear in less than a year. There are periods when there is spotty clearing of the skin, which soon, however, becomes involved again. Finally, after many months, and with little evidence that the disease is influenced by therapy, there is a gradual disappearance of the eruption.

These children often have other allergic manifestations. They are highly susceptible to infection. Infection in the skin plays a dominant role in the inflammatory features of the eruption, as it does in other types of infantile eczema.

**Treatment** is similar to that described under Infantile Eczema. Owing to the chronicity of the disease, rigid dietary restrictions are inadvisable. Treatment of any existing infection is an important consideration. Hill recommends that egg and wheat be removed from the diet, that a mild tar ointment be used on the face and extremities and petrolatum on the trunk, and that the skin be washed twice a day with pHiso-hex. Temporary relief in critical situations can often be obtained from the use of corticosteroid.

## URTICARIA AND OTHER ALLERGIC ERUPTIONS

### URTICARIA

The urticarial wheal (hive), the characteristic allergic lesion, is produced by dilatation and increased permeability of the capillaries. It consists of a central edematous area with areolar flush.

**Etiology.** Allergy cannot in all instances be proved to be the cause of urticaria. It seems to be the factor more frequently in children than in adults, foods being the commonest excitants. Though any food may be causative, seafood, especially shellfish, berries, chocolate, egg and milk are the most common offenders. A food which has constantly produced hives may cease to do so when hyposensitization to it has developed after continual ingestion in its original state, or when its allergic potency has been decreased by cooking or other means. Infection and psychogenic factors, which are said to have etiologic significance in the adult, appear to play a minor role in the child.

Localized hives which result from insect bites are often confused with the allergic form. Irregular distribution on an exposed part of the body, the possible exposure to insect (mosquito) bites and the absence of any family or personal history of allergy suggest this etiology. The ingestion or injection of drugs such as penicillin, the sulfonamides, salicylates, phenolphthalein, barbiturates and arsenicals may also be responsible for an urticarial eruption. The reaction, especially to penicillin, may be delayed until after administration of the drug has ceased.

Urticaria also appears as a reaction to injected foreign serum (serum disease) and vaccine. When it follows blood transfusions, it most probably represents an allergic reaction to some antigen in the blood. Urticaria may be an early manifestation of rheumatic fever and is often associated with the severe form of the disease. It may in rare instances be caused by contact with certain foods, insects and silks, and by inhalants.

Physical allergy, especially to cold, is not an uncommon cause. Hives may occur after a cold bath or exposure to cold winds. This type of urticaria can be reproduced by placing iced compresses on the skin. Heat and sunlight can also produce hives.

Skin testing is of little help in the detection of offending allergens; a careful history and the use of elimination diets are most helpful.

**Clinical Manifestations.** The individual wheal may be a macular, erythematous lesion with little edema, or the edema may be the predominant feature with wide extension and pseudopodia. In the infant, hives are usually of the macular type. In severe urticaria small wheals coalesce into large patches which may cover large areas of the body. Frequently the urticarial wheals come out in crops, the older lesions fading as new ones appear. The eruption and the associated itching tend to be more intense at night. Itching often precedes the appearance of the wheal. The individual hive may persist for a few minutes to several hours or days. Those which persist a long time are more often macular, are pinkish, and have little or no edema. Urticaria may persist for some time after an offending food has been eliminated and in drug sensitivity for weeks after the drug has been stopped. Chronic urticaria is uncommon in childhood; the clinical manifestations are similar to those of the acute variety. Erythema multiforme-like lesions or angioneurotic edema is occasionally associated with typical urticarial lesions.

*Angio-edema (angioneurotic edema)*, or giant hive, is a tense, white, nonpitting edema unassociated with itching; it rarely lasts more than a few hours. It commonly occurs as a localized lesion of the ocular area, lips, ears, side of face, tongue or larynx, or may be diffuse and involve legs and arms. When the larynx is involved, tracheotomy may be required as a lifesaving measure. A familial tendency to the laryngeal form has been reported. It has been described in the newborn infant, but occurs more frequently in older children. Various cerebral and cranial nerve disturbances have been ascribed to angioneurotic edema. It may occur in the Schönlein-Henoch syndrome.

**Treatment.** Treatment of mild hives is entirely symptomatic. A cathartic may be given to hasten the elimination of the offending food, and the diet should be light and limited to accustomed foods. In severe cases epinephrine, especially in oil, may be beneficial, as are the corticosteroids. The antihistaminic drugs (p. 1320) have been particularly helpful in the treatment of urticaria.

Sedatives may be necessary when itching is intense. When a large part of the skin is involved, soothing baths may be helpful. Ice cold applications of bicarbonate of soda paste and calamine lotion are also helpful. In severe and persistent cases the nonspecific measures for hyposensitization in allergic children may

be tried. In children the disease is usually self-limited.

## ALLERGIC RHINITIS

### HAY FEVER, NONSEASONAL ALLERGIC RHINITIS, VASOMOTOR RHINITIS

**Etiology.** The types of noninfectious rhinitis common in adults also occur in children; these include atopic rhinitis (seasonal hay fever or pollinosis), nonseasonal allergic rhinitis resulting from the inhalation of dust and other antigens, and the so-called non-atopic vasomotor rhinitis resulting from intrinsic factors. MacKinney and Glaser found this symptom in about one third of their allergic patients.

**Clinical Manifestations.** Paroxysmal sneezing attacks characteristic of hay fever during the season of pollen prevalence are common in older children, rare in infants. The sneezing attacks come most commonly on awakening and during the early morning hours, but in more severe cases they recur throughout the day, and cease only with sleep. In mild cases stuffiness and itching of the nose may be the sole complaints; in others, in addition to the sneezing, there is nasal congestion and a profuse rhinorrhea of a thin, watery-mucoid material. The nasal mucous membrane is swollen, boggy and pale, at times almost white. With superimposed infection, which is common, a purulent discharge is present, and the mucous membrane is inflamed. Itching of the palate is common. In about one third of hay fever patients asthma is an associated manifestation.

Intense redness, edema and itching of the conjunctiva are not so common in the child

as in the adult, but may be the only symptoms of pollinosis and may occur seasonally in the child for several years before the onset of nasal symptoms. The intensity of the symptoms is not constant during any single day, nor from day to day during the season.

Eosinophilia (5 to 10 per cent) in the peripheral blood is commonly present; it may be found on some days and not on others. Eosinophilia of the nasal secretions of more than 3 per cent has diagnostic significance, since only rarely does it occur in nonallergic states. It may, however, occur without clinical signs of nasal allergy in a child of an allergic family. The swab used for obtaining nasal secretions must be thin and inserted into the posterior part of the nose, and allowed to remain there for about a minute to collect mucus. If the mucous membranes of the nose are greatly swollen, it is wise to shrink them with a decongestant agent before passing the applicator.

**Diagnosis.** The diagnosis of *hay fever* is established by positive skin reactions to specific pollens or fungi known to be present in the atmosphere at the time when the patient displays symptoms (see p. 1307). Though hay fever may be brought on by the ingestion of foods, most cases result from the seasonal inhalation of pollen or fungi. In order to make an appropriate selection of skin-testing antigens, the physician must know the common pollen offenders of his locality and their pollinating seasons. It is uncommon for pollen from wild or cultivated flowers to cause much trouble unless they are brought into the home. The pollens of most of these are transported by bees, butterflies and insects and, probably because of their weight, are not found in the air far from their source. The offending pollens come mainly from grasses and weeds and, to a less extent, from trees.

*Nonseasonal allergic rhinitis*, in contrast to hay fever, is fairly common during late infancy and early childhood. The usual complaint is that the child's nose is always stuffy, that he makes hawking sounds and is constantly rubbing or picking at his nose. These children seem to be unusually susceptible to colds, and postnasal drip and cough may persist for weeks or months after an acute respiratory infection. Infection may involve the sinuses; in older children mucous polyps may develop, and bronchitis with peribronchial thickening is not uncommon. These children tend to have respiratory disturbances

during most of the winter, but are free of them during the summer months, unless they are also pollen-sensitive.

It has been suggested, but not proved, that bacterial sensitization in the allergic child accounts for his peculiar susceptibility to respiratory infections and is responsible for their chronicity. It is not uncommon for children with an inherited allergic diathesis to retain colds for a long time. The allergic feature of nonseasonal allergic rhinitis often becomes apparent only from a careful history. Nasal and blood eosinophilia constitutes supportive evidence. Positive skin tests to one or more of the common environmental inhalants, such as house dust, feathers, cosmetics and animal hair, are usually obtained.

*Nonatopic vasomotor rhinitis* bears a close clinical resemblance to nonseasonal allergic rhinitis. True atopy, however, cannot be demonstrated, and a positive family history is usually lacking. Vasomotor rhinitis is more common in adults than in children. Some believe that this type of rhinitis results from certain intrinsic factors, as, for example, a low basal metabolic rate, and cite as evidence the relief some adults obtain with thyroid medication. These patients are especially sensitive to cold and drafts; their disturbance may be a sort of physical allergy.

**Treatment.** Measures for the treatment of hay fever have been outlined under Treatment of the Allergic State (p. 1309). The most desirable measure would be complete elimination of the antigen from the environment. However, because the commonly offending grasses and weeds are widespread, this is usually impossible. A decrease in the amount of inhaled pollen can be obtained by filtering the air coming into the room where the child spends all the night and several hours of the day. Since pollination of grasses and weeds is heaviest in the early part of the day, it would be best to keep the child's room closed during these hours and open it in the early evening. When possible, removing the child to a section of the country where the pollens to which he is sensitive do not exist is ideal. When the prevailing winds are from the ocean, the seashore may bring some relief. Long residence in a new section of the country, however, though removing the patient from old antigens, may bring him into contact with new ones to which he becomes sensitized.

Hyposensitization to the specific pollen or pollens to which the patient has been found sensitive should be tried when the preceding

measures do not bring satisfactory relief. When the child is sensitive to many pollens of a given species, treatment with a single representative of the group, because of cross immunization, is usually sufficient. The dosage to be used and the course of injections to be given are described on page 1309. Instillation of constricting agents into the nasal passages brings temporary relief. Aspirin is often helpful when sleep is disturbed. The various nonspecific measures designed to decrease the responsiveness to allergic reactions (p. 1311) are helpful in controlling the more severe cases.

The antihistaminic drugs are helpful adjuncts in the treatment of seasonal hay fever. Hyposensitization and antihistamine therapy may be combined. The dose of antihistaminic drug varies with each patient and, in a given patient, with the symptoms. Relief may be obtained with one antihistamine when another is unsuccessful; long-acting antihistamines are available. Side effects of antihistamines are fatigue, drowsiness, headaches, dizziness, gastrointestinal symptoms and occasionally insomnia, diarrhea or palpitation. Agranulocytic changes have been observed with long-continued administration of Pyribenzamine.

In nonseasonal allergic rhinitis attempts must also be made to determine offending allergens by a detailed history and by skin testing. Treatment consists in removing the offending antigen, such as house dust, fungi or animal danders, from the environment or in hyposensitization by serial injections. A positive skin reaction to dust is commonly obtained in this condition, and treatment with a stock dust extract or preferably with one prepared from dust collected in the patient's home by means of a vacuum cleaner is often beneficial.

In summer, when respiratory infections are at a low ebb, the patient with nonseasonal allergic rhinitis is usually free of symptoms. Autogenous bacterial vaccines made from nasopharyngeal cultures or from bronchoscopic aspirations and given at regular intervals over most of the fall and winter months have seemed to be of benefit in some instances, but there is also considerable skepticism concerning their effectiveness. The combined injection of dust extract and a bacterial vaccine has seemed to be better than the use of the vaccine alone. Some observers believe that vaccine therapy is beneficial in a non-specific manner. Tonsils and adenoids should be removed only if infected; the operation

should not be performed during pollen seasons, since there is suggestive evidence that asthma may be induced in this manner in allergic children.

In persistent and severe cases removal of the patient to a warm, dry climate for the fall, winter and early spring seasons may be distinctly beneficial. The child will, of course, retain his allergic sensitizations, and nasal catarrh may persist. As the child grows older there is a tendency to lose the susceptibility to infections, and the catarrhal symptoms become less prominent, though hay fever or asthma may develop.

## ASTHMA

**Etiology.** Asthma is an allergic pulmonary disorder characterized by paroxysms of an expiratory type of dyspnea with wheezing and by generalized obstructive emphysema. The similarity between induced anaphylaxis in the guinea pig and human asthma strongly suggests a common mechanism for these two conditions. Infantile eczema and allergic rhinitis are common forerunners of asthma.

There is an apparent tendency in allergic persons for areas of localized edema to develop, especially in their upper and lower respiratory passages; this has been termed the "exudative diathesis." Frequently, after hearty laughter or vigorous activity, they have considerable secretion in their bronchi which produces a cough and, in some instances, mild respiratory distress with wheezing respirations. Exposure to cold, inhalation of cold air, smoke or mildly irritating gases may also induce a mild asthmatic attack. Psychic factors also seem to play an important etiologic role; smooth muscle and vasomotor tone are greatly influenced by emotional factors.

The frequency with which respiratory infection precedes the asthmatic attack has led many workers to consider bacterial sensitization the most important cause of asthma in children. There is little evidence to support this view, but considerable that infection often precipitates the asthmatic attack.

The common occurrence of asthmatic attacks at night has been variously explained. In some cases nocturnal attacks may depend on the presence of a feather pillow, cotton mattress or other inhalant antigen in the bedroom. Another possibility is that during sleep the cough reflex is depressed, permitting secretions to accumulate and obstruct the bronchial lumens, or the reduced vital capac-

ity resulting from the horizontal posture may also help to induce respiratory distress.

**Pathology.** The greatest changes are in the smaller bronchioles. In the early stage of the acute attack the essential changes are spasm of the bronchiolar musculature and edema of the mucous membrane, each of which obstructs the flow of air. The mucous membrane is pale and boggy. As the attack continues, thick, tenacious mucus fills the tubes, further obstructing the passage of air. In the acute case the muscular spasm soon relaxes, the patient coughs up the mucus, and the attack subsides within a few hours to two or three days. When infection is present, vascular congestion and polymorphonuclear infiltration of the bronchial walls, with increased exudation into the bronchial lumen, increase the respiratory embarrassment.

During the asthmatic attack not all the inspired air is exhaled; some of it is trapped in the alveoli, resulting in generalized obstructive emphysema. Wheezing results from air passing through the narrowed bronchiolar lumens, and rales are produced by the bronchial secretions. One or more of the larger bronchi may be completely obstructed by tenacious mucus, in which case atelectasis may develop. In the chronic forms of asthma, which are uncommon in children, the lining of the bronchioles is thickened by increased vascularization and eosinophilic infiltration. The goblet cells are increased; hyalinization of the basement membrane occurs, and the musculature and mucous glands are hypertrophied. As a result of long-standing respiratory obstruction, persistent emphysema develops. The dome of the diaphragm is depressed, reducing its functional activity, the ribs are maintained in the position of inspiration, and the respiratory effort becomes ineffective. When an acute asthmatic episode supervenes, breathing is almost impossible, and death from cardiac failure may occur.

**Differential Diagnosis.** As Jackson has emphasized, all that wheezes is not asthma. An aspirated foreign body may produce a distinct respiratory wheeze which must be differentiated from that of true asthma. Cardiac asthma is rare in children.

In so-called *asthmatic bronchitis* there is a certain amount of respiratory distress and wheezing, and musical rales are present on auscultation. There is no eosinophilia and no relief from epinephrine. In some children this tendency is so marked as to suggest a peculiar constitutional type of reaction. As

the child grows older the tendency to spasmodic bronchitis disappears. During the first attack it is not always possible to determine whether allergic asthma is a factor. The presence of a positive personal or familial history of allergy, of eosinophilia, and of response to epinephrine suggest an allergic basis for the attack.

Generalized obstructive emphysema in infants is most often due to factors other than allergy, such as primary bronchiolitic infection or infection superimposed upon aspiration pneumonia or infection associated with cystic fibrosis of the pancreas.

**Clinical Manifestations.** Asthma is uncommon in infancy, becoming more frequent after two or three years of age. Attacks of asthma which do occur in infants may be somewhat atypical. Acute respiratory distress, more evident in expiration, with shocklike symptoms may constitute the principal manifestation. Wheezing and musical rales may be absent. It is essential to recognize that asthma may present such a clinical picture in the infant and that the administration of epinephrine may be lifesaving. When the asthmatic attack is due to pollen sensitivity, there is little difference in the symptomatology of the child and the adult. Nasal congestion with sneezing and watery discharge usually precedes the attack by a few hours to a few days, and the child is often thought to have a head cold. Fever is usually absent, even in the presence of active infection. A slight cough may precede the attack, at this time musical rales may be heard, and the patient may complain of a sense of heaviness in the chest.

An attack of asthma may be ushered in with great suddenness, often during the night, with respiratory distress and noisy, wheezing breathing. The older child sits up in bed in an effort to secure better aeration. Sweating is prominent, the facial expression anxious, and the child appears in great distress. Respirations are thoracic; the chest is distended and the abdomen fixed. Expiration is prolonged, and most of the wheeze occurs during this phase of breathing. A short, ineffective or deep harassing cough may be more or less continuous, further exhausting the child.

The chest is hyperresonant to percussion, the breath sounds are weak, and when little exchange of air occurs, not much wheezing will be heard. Sibilant and musical rales often obscure the breath sounds. Occasionally a

bronchus becomes plugged with the thickened tenacious mucus and produces atelectasis in the supplied lobe. The mediastinum is then shifted toward the involved side. Heart action is rapid and during severe attacks may be weak; cardiac failure is uncommon in children. The neck veins are distended, and cyanosis may be marked.

When treatment is effective, the attack may be abruptly terminated. Otherwise it may continue for several days, gradually decreasing in intensity, but often with intervals of exacerbation.

The sputum may contain plugs of mucus in spirals, and eosinophils. The blood cell count in uncomplicated cases is little changed except at times for a moderate increase in eosinophils. In the absence of infection the erythrocyte sedimentation rate is normal.

The presence of acute infection modifies asthma in many ways. The onset is less abrupt, but the difficulty in respiration progressively increases to the typical asthmatic type. The response to epinephrine is poor, owing to the inflammatory changes. Fever and leukocytosis are likely to be present. Recovery is slow, and it is often a week or several weeks before the patient is completely restored to good health. Musical rales and cough persist long after evidences of dyspnea have gone. Recurrent attacks of bronchopneumonia may complicate the course of chronic asthma, and roentgenograms taken between acute episodes show evidence of bronchial and peribronchial thickening.

*Status asthmaticus* is intractable asthma which may persist for days with little relief even during sleep, resulting in great exhaustion of the patient. In rare instances it may occur early in the course of asthmatic disease, but is more common in cases of long standing. Death from asthma is rare, but may occur during status asthmaticus.

**Prognosis.** Though there is a tendency for asthma in children to subside at puberty, many cases continue throughout life and even become worse. Children who lose their asthma may acquire hay fever or some other allergic phenomenon. Allergic sensitivities change; the child who loses his sensitivity to foods may become sensitive to an inhalant.

The prognosis of asthma is greatly influenced by management, especially when one is able to identify a causative antigen or antigens. Best results are obtained when treatment is begun early. In some instances there appears to be some intrinsic factor which

cludes control and makes the prognosis less hopeful. Chronic respiratory infection obviously has an unfavorable influence.

Rackemann and Edwards determined the status of 449 adults twenty years after the onset of asthma during childhood. Of these, 30 per cent were entirely relieved of their symptoms; 19 per cent had no symptoms because they successfully avoided the offending causes of their asthma; 21 per cent no longer had asthma, but had some other allergic manifestation, usually hay fever; 26 per cent still had asthma of some degree, but in only 11 per cent was it considered serious; only 1 per cent had died of asthma. Asthma seen after thirteen years of age tends to have a less favorable prognosis.

**Treatment.** The most successful therapy is elimination of the offending allergens. Since in many cases the allergens cannot be determined, and in others cannot be successfully removed, other methods of treatment must be applied. Hyposensitization to antigens thought to be causative as revealed by a carefully taken history, by skin tests or by elimination regimens is often successful. The methods of testing for specific allergens and for hypersensitivity have been described on page 1307. Though asthma is more often caused by inhalants than by ingested foods, elimination diets are at times indicated as diagnostic and therapeutic procedures. Complete or partial elimination of pollen or other environmental allergens as described under the treatment of allergic rhinitis is often effective in preventing the asthmatic attack. Nonspecific methods to decrease the responsiveness of the allergic patients (p. 1311) should be carried out. When such factors as exertion, emotional upsets, exposure to cold and inhalation of irritating gases and chalk have been found to induce an attack, they should be avoided.

Epinephrine is by far the most effective drug for the relief of asthma, improvement usually being manifest within a few minutes after its injection. There is no reason to withhold it until the attack has become severe or the child is exhausted. There is little evidence that doses of 0.2 to 0.3 cc. of a 1:1000 solution, injected hypodermically several times a day for many days, are harmful. Small doses are as effective as larger ones in relieving the asthmatic attack, will not evoke the disagreeable side effects of pallor, tachycardia and sweating, and may be repeated every hour or half-hour if necessary. Though the response to epinephrine is not so striking when an in-

fection is present, it should still be administered.

Long-acting preparations of epinephrine in oil, 0.5 to 0.7 cc. of the latter, injected intramuscularly, may provide relief for twelve to sixteen hours. If a separate injection of the standard epinephrine is made simultaneously with the first injection of the one in oil, an immediate as well as a prolonged effect may be obtained.

Epinephrine may also be effectively administered by pharyngeal spray in a 1:100 dilution by the parent or the older child himself. A special glass nebulizer is required; benefit will result only if the epinephrine is sprayed deeply into the pharynx at the time of a full inspiration. Two or three compressions of the bulb of the atomizer will deliver sufficient epinephrine to bring relief of symptoms within a few minutes. If need be, the application may be repeated in one-half to one hour, but too frequent use may injure the bronchial mucous membrane. Under no circumstance should the 1:100 dilution of epinephrine be injected hypodermically; serious or even fatal reactions may occur.

There is rarely indication for the intravenous administration of epinephrine. It may be used as an emergency measure in severe status asthmaticus, but even in this case only small amounts diluted in saline solution should be injected intravenously.

Occasionally some resistance to the therapeutic effect of epinephrine is acquired after prolonged use, and larger doses are required to obtain the desired effect. The temporary use of aminophylline has been said to restore the normal reaction to epinephrine.

Ephedrine sulfate or hydrochloride is useful in controlling mild attacks of asthma and for the relief of cough. The dose for infants is about 8 mg. and for older children 15 mg. Ephedrine, 15 mg., may be combined with phenobarbital, 15 mg., and aminophylline, 30 to 60 mg., in a cough syrup (doses are average for a child of five years). Some believe that acetylsalicylic acid heightens the effect of ephedrine and combine the two in powders. Aqueous solutions of ephedrine may be used locally for the relief of nasal congestion.

Aminophylline (ethylenediamine) is an effective bronchodilator. In severe cases it may be injected intravenously in doses of 3.5 mg. per kilogram. The injection should be given slowly over a period of at least ten minutes. It may be administered undiluted, but preferably should be diluted in 150 to

200 cc. of 10 per cent glucose solution. If vomiting is induced, subsequent doses should be smaller or injected more slowly. It may not be repeated in less than six hours, and preferably less frequently. Nausea, circulatory disturbances and syncope may result from overdosage, and fatalities have occurred. Aminophylline is especially indicated when epinephrine has lost its effectiveness. It may be given orally in doses of 5 mg. per kilogram for the control of mild episodes or as a prophylactic measure, when it may be combined effectively with ephedrine and phenobarbital. Good results may also be had with rectal administration of aminophylline in a suppository in doses of 7 mg. per kilogram.

Antihistaminic drugs are useful in the treatment of asthma, but less so than in hay fever or urticaria.

In severe and uncontrollable asthma, especially in status asthmaticus, a corticosteroid may bring about dramatic relief. Improvement is often noted within four or five hours, but may be delayed. Therapy in full dosage may be necessary for only a few days, since benefit may persist after treatment has been stopped. In the chronic forms of asthma more prolonged therapy with smaller doses may be necessary. During hormonal therapy other methods of treatment should not be neglected.

The atropine group of drugs dries secretions and makes their expectoration more difficult. These effects often outweigh the benefits obtained from decrease in the spasm of bronchial musculature.

Fumes from the combustion of stramonium leaves may relieve a mild attack, but other forms of therapy are so much more effective that this method is now little used.

Potassium iodide is a valuable drug in the treatment of long-standing asthma because of its property of liquefying bronchial mucus. The drug should be given in increasing doses until there is an increase of bronchial secretion, and then the dose reduced slightly so that overproduction of mucus will not aggravate the cough. The patient should be watched closely for toxic effects; if these occur, the drug should be discontinued. Syrup of ipecac may also be used as an expectorant; if vomiting is produced, other expectorants may be used. When secretions are sticky and thick, it is important to provide a generous fluid intake.

Sedation is often necessary during the asthmatic attack so that apprehension may be

relieved and sleep obtained. Phenobarbital can be used with safety in relatively large doses. Chloral hydrate is useful when the patient is stimulated rather than sedated by barbiturates. Morphine should never be used during an asthmatic attack, since it produces bronchial spasm and may so depress the cough reflex that the child is actually drowned by the accumulated secretions. Paraldehyde diluted in olive oil and administered rectally is a most effective and prompt sedative, an effect usually being produced within fifteen minutes and lasting ten to twelve hours. Overmedication must be avoided.

Oxygen is of great value in reducing anoxia and cyanosis and is best administered in a tent. Its effectiveness is said to be increased when given in combination with helium in a ratio of 20 per cent oxygen to 80 per cent helium. The combination of carbon dioxide in a 10 per cent mixture with oxygen is said to be of help in liquefying the mucoid secretions. The humidity of the room atmosphere or oxygen tent should be kept relatively high.

In status asthmaticus when all else fails or when extensive atelectasis exists as the result of a plugged bronchus, bronchoscopic aspiration may free the airway.

When bacterial infection complicates the asthmatic episode, specific antimicrobial therapy is indicated. Every effort should be made to prevent respiratory infections as a prophylactic measure for the reduction of asthmatic attacks. Removal to a warm, dry climate during the winter season may be the only means of reducing the incidence of respiratory infections. A feather pillow, however, may cause as much trouble in the deserts of Arizona as on the damp, windswept North Atlantic coast.

Bacterial vaccines have been used extensively in attempts to reduce the incidence of respiratory infections and to induce hypersensitization to bacterial antigens. Theoretically, autogenous vaccines prepared after determining sensitivity to the organisms by skin testing should be more effective than the usual stock vaccines. In most cases vaccine therapy seems of little value. Most observers feel that beneficial results, if any, are due to nonspecific effects, and some suggest the use of a single bacterial vaccine (*Staphylococcus*) in all cases. The combination of dust extract with a bacterial vaccine is widely used.

In patients with recurrent or chronic asthma, when infection in the upper respiratory tract is difficult to control and the adenoid tissue is hyperplastic, irradiation

with radium is used to reduce the lymphoid hyperplasia. This method is not without serious danger and certainly is at best rarely indicated and should be used only by persons skilled in the use of radium.

In all cases the general health of the child should receive adequate attention. This includes a properly balanced diet and the proper amount of sleep at night, and afternoon rest periods when they are indicated. Attention should be given to the control of house dust and other inhalants within the home, including strong odors from foods to which the child is sensitive. Removal of animal pets with fur or feathers from the household regardless of the results of skin tests is essential.

Emotional factors play a significant role in the production of asthmatic attacks, and family guidance and psychotherapy are often of great benefit.

#### SERUM SICKNESS

**Etiology.** Serum sickness will occur in nearly all persons, whether atopic or not, provided the amount of foreign serum injected is sufficiently large. When 100 ml. or more of foreign serum are given to an adult, serum sickness will occur in 90 per cent of instances. If less than 10 ml. are given, only about 10 per cent of persons will have a reaction. Fresh serum evokes a stronger reaction than older, stored serum. The Negro

and the American Indian are said to be less susceptible than the white race, but age and sex do not appear to be influencing factors.

The serums from different animals vary in their capacity to evoke reactions. By far the commonest cause of serum sickness is the parenteral administration of horse serum. Hog serum is as antigenic as horse serum; beef serum produces fewer reactions; avian serum is reported to produce none at all, and human serum rarely produces serum disease. Penicillin may infrequently induce a similar clinical response.

The most widely accepted explanation for serum sickness which follows the first and only injection of a foreign serum is the one proposed by von Pirquet and Schick: The injection of the serum incites the production of antibodies, which unite with the remaining portion of antigen (serum) to produce the allergic reaction. Passive transfer antibodies appear about the same time (eight to twelve days) as specific precipitins. Heterophile antibodies are also frequently present after the administration of horse serum. These antibodies may persist for years.

In persons previously sensitized to horse serum a subsequent injection of this serum usually induces an immediate reaction. Minute amounts of horse serum (such as is contained in diphtheria toxin-antitoxin) are sufficient to sensitize a person for years. The ingestion of horse serum or horse meat also incites sensitivity to horse serum. Such persons react immediately or within a few hours after the injection of serum. The reaction is likely to be more severe than in the usual serum sickness and may be fatal. Most fatal reactions, resembling anaphylactic shock, have occurred in atopic persons sensitive to horse serum or dander.

Necrotizing arteritis and periarthritis of the small arteries and endocardial lesions have been described.

**Clinical Manifestations.** The reaction usually follows an average incubation period of about seven days; however, it may occur within a few hours or may be delayed as long as thirty-six days. The most striking or characteristic symptom is the skin eruption, the most common lesion an urticarial wheal. These occur first at the site of the serum injection and may spread out in concentric rings. Soon the eruption appears over the entire body, being more prominent in regions of local pressure. Less commonly the eruption may be erythematous, morbilliform or scarlatiniform. Rarely an exanthem occurs; its

absence is a differential point from the various exanthematous diseases. Purpura and exudative eruptions may occur in the more severe cases.

Angioneurotic edema often is a striking feature of the reaction. It may be limited to the eyelids, lips, tongue, pharynx, hands or feet, or it may be generalized, resembling the edema of nephrosis. Itching is marked in practically all instances. Generalized lymphadenopathy is frequently present, and the enlarged nodes are tender, especially those draining the injected area. The spleen is often enlarged. Swelling, redness, pain and stiffness of the joints, usually the larger ones, are not infrequent; a single joint may be involved. There may be widely distributed muscular pains, and headache and malaise are frequent. Fever may be an early or late manifestation, at times antedating the eruption by two or three days. It is usually remittent and varies considerably in degree. When it appears before the onset of the eruption, much diagnostic confusion may arise. In severe cases neurologic complications such as neuritis, polyneuritis and cerebral manifestations with delirium, vomiting and convulsions have been described. Evidences of damage to the central nervous system have persisted for several months. The blood shows a slight leukocytosis often followed by leukopenia with eosinophilia. The erythrocyte sedimentation rate is usually moderately elevated.

Serum sickness in the previously sensitized person usually presents the same symptoms as in the nonsensitized except that they are manifest within a few hours and are more often associated with asthmatic symptoms and circulatory disturbances resembling anaphylactic shock.

**Prognosis.** Serum sickness is a self-limited disease. In the usual case it lasts one to three days; in about one third of the cases it lasts four to seven days, but may last even longer. In some instances the symptoms may subside and recur once or twice after intervals of a few days; a plausible explanation is that various fractions of the serum have different "incubation" periods.

**Prevention.** Before the injection of any foreign serum, the recipient should be tested for sensitivity. Normal horse serum rather than the therapeutic horse serum should be used, since falsely positive reactions may occur when the therapeutic serum is used as the testing material. An intradermal injection of 0.02 ml. of a 1:10 dilution of horse serum should be made. When there is a history of

asthma, hay fever or some other allergic disease, or when a hypersensitivity to horse serum or dander is known to exist, 0.02 ml. of a 1:100 or, preferably, a 1:1000 dilution of the serum should be used. If the weaker dilutions do not induce a reaction, a stronger one should be used after twenty minutes. In hypersensitive persons even this small amount of serum may produce severe generalized or even fatal reactions. Hypersensitivity varies, and the person may be able to take the second injection of serum with little effect. With a history of horse dander sensitivity, therapeutic serums from another animal species should be secured if possible. The ophthalmic test may also be used as a guide in determining the degree of sensitivity in the patient, using a drop of a 1:10 dilution for the first test and undiluted serum for the final test. Antihistaminic drugs have been recommended as prophylactic agents in serum disease.

**Treatment.** Epinephrine should always be available when the skin test is made for serum sensitivity or when serum is injected. It is of great value in controlling the anaphylactic symptoms as well as the urticarial eruption. Several doses may be required to keep the symptoms under control. Ephedrine may be used in the milder cases or after epinephrine has partly controlled the symptoms. The antihistaminic drugs and, in severe cases, a corticosteroid should be given for about seven days.

Cold compresses of a 5 per cent solution of sodium bicarbonate and starch baths help relieve the itching. Histaminase may be tried, but has not been particularly effective. Salicylates and sedatives may help make the patient more comfortable.

#### GASTROINTESTINAL ALLERGY

**Etiology.** Gastrointestinal symptoms, such as vomiting and diarrhea, may accompany

other allergic manifestations, and under these circumstances do not necessarily represent an antigen-antibody reaction in the intestinal wall as the shock organ. There are instances, however, when the gastrointestinal tract does represent the shock organ in the allergic response, and the symptoms produced depend on such typical lesions of atopy as edema, excessive secretion of mucus and smooth muscle spasm in the intestinal wall. Edema of the tongue and palate has been noted when certain foods are eaten. Topical application of foods to exposed intestinal mucosa (colostomy) or the rectal mucosa through a proctoscope in sensitized persons produces localized edema with discharge of mucus. Intestinal spasm has been demonstrated roentgenographically, and pylorospasm by increased gastric peristaltic waves, when offending allergens are ingested.

The frequency of gastrointestinal allergy is difficult to estimate, owing to the varied causes of diarrhea, vomiting, colic and abdominal pain in children and the limitations of specific diagnostic procedures.

**Clinical Manifestations.** The chief manifestations of gastrointestinal allergy in children are vomiting, colicky abdominal pain, and diarrhea. Colicky pain and diarrhea, the stool containing much mucus and sometimes blood, are more characteristic of intestinal allergy in young infants. Fries points out that the portion of the alimentary tract involved determines the location of the abdominal pain. There is wide disagreement as to the frequency with which infantile colic is caused by allergic hypersensitivity; most observers believe it is infrequent.

In a group of newborn infants who had allergic intestinal symptoms after sensitization to cow's milk the clinical pictures were strikingly similar. About three weeks after cow's milk feeding had been instituted colic appeared and became progressively worse. The infants seemed excessively hungry, but gained weight at more than the usual rate. Within a few days after the onset of abdominal symptoms, loose stools appeared and soon contained mucus and bright red blood. The amounts of blood varied from small pinhead-sized clots well mixed with the slimy stool to profuse hemorrhage containing no fecal matter. In two patients the colicky pains were associated with visible, large, gastric peristaltic waves, indicative of pylorospasm. The bleeding and clotting times were normal. In each case there was prompt and complete disappearance of the blood from the stools

within forty-eight hours after withdrawal of cow's milk from the diet. The mucus in the stools and the colic disappeared shortly afterwards. Most of these infants subsequently had eczema; one had asthma. Bachman and Dees consider cow's milk responsible for most instances of gastrointestinal allergic disorders.

Symptoms resembling those of celiac disease are infrequent in older infants with milk allergy. Davidson and Burnstine reported a celiac-like disorder in a three-months-old infant fed cow's milk. The disturbance was characterized by steatorrhea in which both saturated and unsaturated fatty acid fractions increased in the stool with ingestion of milk. They demonstrated that steatorrhea occurred when betalactoglobulin was fed, and the diarrhea and steatorrhea were relieved when the substance was removed from the diet. This is one of the few instances in which a celiac-like syndrome was proved to result from ingestion of a purified protein substance. The celiac syndrome induced by the feeding of wheat and rye gluten is considered not to be a hypersensitivity phenomenon by most workers. This does not preclude the possibility that celiac disease may be caused by hypersensitivity to other foods.

Henoch's purpura with hemorrhage, edema of the intestinal wall with occult blood in the stools, and ecchymoses in the peritoneum are occasional allergic manifestations. Mucous colitis is occasionally seen, and the so-called spastic colon is not an uncommon finding in asthmatic children.

**Diagnosis.** There is too great a tendency to brand all sorts of gastrointestinal disturbances as allergic; the diagnosis of gastrointestinal allergy is most difficult to prove. The diagnosis is aided if there is a family history of allergy or if the patient evidences other allergic manifestations. Skin tests are generally unreliable. Diagnosis is based principally on the disappearance of symptoms when a suspected food is removed and on the return of symptoms when it is again ingested. This therapeutic test has greater significance when the test substance is as purified as possible and is in small quantity. An intestinal disorder following food ingestion does not prove the existence of allergy; the disorder may result from food "intolerance." The leukopenic index does not seem to be a reliable test for the demonstration of food allergy. Large numbers of eosinophils in the mucus of the stools are suggestive of allergy in persistent gastrointestinal disturbances; their absence does not exclude the diagnosis.

**Treatment.** Treatment of gastrointestinal allergy consists in elimination of the offending food. When an essential food is involved, substitution must be made with discrimination; in place of cow's milk, goat's milk or one of the milk substitutes may be prescribed. When the symptoms are mild, alteration of the antigenicity of cow's milk by cooking may suffice. Oral hyposensitization may be successful. Belladonna or one of the other antispasmodics may be helpful in counteracting intestinal spasm. In allergic families every effort should be made to have the infant breast-fed.

# The Eye

## EYES OF THE NEWBORN INFANT

The eyes at birth are physiologically and anatomically immature. This immaturity is only relative, since the body as a whole grows seven times as much as the eyes after birth. Furthermore, the eye develops earlier and more fully in the embryonic stage than do most other parts of the body.

At birth the eye is three quarters of the adult size. The orbital outlet is circular rather than horizontal. The cornea measures 10 mm., compared with the 12-mm. diameter of the adult cornea. The sclera is thin, resulting in a bluish tint. The lacrimal gland is small, and no tears appear when the baby cries until the third or fourth week after birth. The macula is not completely developed until shortly after birth; the fovea continues to be further differentiated for about sixteen weeks. The angle of the anterior chamber contains mesodermal tissue, in some cases until the third postnatal month. Medullation of the optic nerve is not completed until the third postnatal month.

The eyes remain closed most of the time in the early postnatal days and are sensitive to light. By the end of two weeks the infant is able to look at large objects, but does not follow them. By four or five weeks he can look at relatively small objects, and by eight to ten weeks he follows moving objects and turns his head away from bright light. Then there is a gradual increase in visual acuity, binocular vision and binocular movements, including rotations, convergence and conjugate movements.

The baby's eyes should be examined with and without dilatation of the pupils, preferably before he leaves the hospital.

The neonatal fundus, particularly in the premature infant, shows gray pallor of the nerve head, absence of pigment and grayness in the periphery of the retinas; the veins and arteries are more nearly alike in size and color than in the adult. Remnants of the hyaloid artery and of the pupillary membrane

are more marked in the newborn and continue to atrophy.

Intracranial hemorrhage in the newborn is usually associated with hemorrhage in the fundus without papilledema. Unfortunately the fundus is rarely examined to detect this diagnostic aid.

## EXAMINATION

**General Examination.** Examination of the eyes of a child can be more thorough than is generally believed.

The *eyelids* are examined for crusts, ulceration of the margins and position of the lacrimal puncta. Pressure with the index finger over the lacrimal sac may express mucous or mucopurulent material through the puncta. The ability to open and close the lids should be tested.

The *conjunctiva* is examined for color, smoothness, thickness, secretion, injection, follicles and papillae, and for the presence of a foreign body. Everting the upper lid is a maneuver worth learning to execute smoothly. The child is asked to look down at his toes; the examiner then grasps the lashes with his right thumb and index finger; he pulls the lid downward and away from the globe, placing a probe, or his other index finger, at the upper level of the tarsal plate. The right fingers pull the eyelid upward and slightly outward, over the finger or probe. The lid is kept everted by holding the thumb against the brow and reminding the child to keep looking downward. Foreign bodies are usually found in the concavity just above the margin of the lid.

The *sclera* is examined for blueness, indicating thinness. The intraocular pressure can be estimated by palpation with both index fingers through the skin of the lid above the tarsus. It can be measured accurately only with a tonometer after local anesthesia (Pontocaine or Ophthaine, 0.5 per cent) or under general anesthesia.

The *cornea* is examined for luster, ulcera-

tion, foreign body, new blood vessels, and scars. The diameter of the cornea should be appraised. Megalocornea is a benign condition to be differentiated from a large cornea which is part of generalized enlargement of the globe in congenital glaucoma. Microcorneas are often associated with other congenital anomalies and sometimes herald glaucoma. Keratoconus is not common in children.

The *anterior chamber* is examined for depth by estimating the distance between the cornea and the iris. A small bright beam of light held at an oblique angle while the examiner looks through a magnifying glass will detect cells or fibrin or vitreous in the chamber.

The *iris* should be examined for color, surface markings and for reaction to light and to accommodation-convergence. The latter is tested by observing both pupils in equal light while the patient looks at a distant object and then at the examiner's finger. Adhesion of the iris to the cornea or the lens should be looked for.

The clarity of the *lens* can be examined by the ophthalmoscope with a plus 8 lens held a few inches away from the patient's eye.

**Fundal Examination.** Dilatation of the pupil is essential for adequate examination of the *fundus*, especially in children who tend either to watch the ophthalmoscope light or to look around the room. Dilatation can be done quickly and effectively with one drop of 5 per cent Neosynephrine plus 5 per cent eucatropine (Mydriatin or Eucadryl) in a solution of methyl cellulose. Homatropine is also effective, but atropine is not safe for the newborn infant except in ointment form, which prevents absorption from the nasal mucous membrane. Cyclogyl is an excellent cycloplegic agent. The lens and vitreous are examined for opacities. The nerve head is examined for shape, color, character of its margins, type of cupping and evidence of edema. The macula should be examined for the cherry-red spot of Tay-Sachs disease and for chorioretinal lesions which usually indicate toxoplasmosis. Each vein and artery should be followed from the disk to its termination. Much more of the fundus can be seen if the child is directed to look up, down, right, and left as the doctor examines the corresponding portions of the fundus. One should not hesitate to examine children under general anesthesia if the information desired is of sufficient importance. If the examination is done under anesthesia, it is

essential to have forceps to steady and move the globe, which rolls upward during sleep.

**Visual Tests.** Testing of visual acuity can be accomplished after three and one-half years of age by the use of a Snellen **E** chart, consisting of rows of the letter **E** in various sizes corresponding to the regular visual test chart. The **E**'s have their "fingers" pointing upward, right, down, and left. Cooperation is obtained more easily by having the child place his fingers on the chart itself, indicating the position of the "fingers" of a few of the **E**'s; the chart is then moved 20 feet away, and the child is asked to continue to show which way the "fingers" point by extending his own fingers in the same direction. Picture charts are less accurate.

Before the age of three and one-half years vision can be determined roughly by testing the pupillary reactions to light or by determining the response of the child to a rubber ring, a 1-inch cube or marbles of various sizes and colors. His ability to watch a light with each eye separately is another good rough measure of visual acuity. If the child loses interest or behaves badly when one eye is covered, but cooperates well when the other eye is tested, vision is probably reduced considerably in the first eye.

The *field of vision* can be tested by the confrontation method until the child is old enough to cooperate on a perimeter. With patience and a projection-type of perimeter accurate visual fields can be elicited at an earlier age than one would suppose.

*Color blindness* can be tested by use of colored wools or having a child trace numbers on an Ishahara or A.O. Color Chart with his finger. Defective color vision is much more frequent in the male than in the female. "Color ignorance" refers to inability to tell shades of color; this condition responds to education.

Mothers inquire about and suspect *mirror vision* far more often than it occurs. It is probable that children often reverse letters on an experimental basis, just as they use toys in unexpected ways. This is a transient form of mirror vision. Rarely one sees a child who actually has true mirror vision. Patient re-education of the child's reading habits is then necessary. The parents should be reassured that the eyes and brain are both normal, and that the problem is to teach the child to interpret what he sees as other people do.

Subnormal *dark adaptation* is difficult to test in young children. Vitamin A deficiency is the only causative condition amenable to

treatment. Retinitis pigmentosa and choroideremia and atrophy of the optic nerve represent reduction in the peripheral field, rather than poor dark adaptation.

**Examination by the Child's Physician.** Routine examinations of the eyes should include (1) the use of a Snellen E or letter chart; (2) examination of motility of the eyes by checking rotations, the near-point of convergence and movements with the cover-test as described under *Strabismus*; and (3) examination of the media and fundi with an ophthalmoscope.

Visual screening tests of children in offices and in schools has proved to be effective. The Atlantic City eye test\* can be done rapidly, provides adequate information, does not require a skilled examiner or extensive equipment and is readily interpreted. It tests visual acuity and muscle balance and provides a rough test of the child's refractive error. After testing the visual acuity with the Snellen chart, a + 1.75 lens is placed before each eye. If the child can then read the preferred chart, he *fails* the test. The muscle balance is checked by the use of a green rectangle in which a red dot should be seen. If the red dot is outside the rectangle, the child has more than one prism diopter of hyperphoria or more than 4 prism diopters of esophoria or exophoria. Children who have any abnormality should be referred for more precise diagnosis.

**Examination by an Ophthalmologist.** The optimal schedule for examination by an ophthalmologist is (1) in the neonatal period; (2) before entering school (age four years); (3) at or just after puberty; and (4) about eighteen years. In addition, examination is indicated whenever vision for either distance or nearness is defective; whenever strabismus is noted, since poor vision from disuse is usually not correctible after the sixth year of life; and at any sign or symptom of disease of the eye.

**Cycloplegics** which are used include atropine, 0.5 to 1.0 per cent, scopolamine, 0.2 per cent (each in an ointment rather than solution to lessen absorption from the nasal mucosa) and homatropine, 4 per cent, in children over twelve years of age. Cyclogyl, however, is the one of choice at all ages. It is almost as effective as atropine, acts more rapidly and paralyzes accommodation for only twenty-four hours, as compared with five days for atropine and scopolamine.

\* Can be obtained from William Freund, 1415 Pacific Ave., Atlantic City, N.J.

**Table 117. Common Ocular Therapeutic Agents\***

*Irrigating Solution*

For ocular irrigation: physiologic saline solution

*Astringent Solution*

	Gm. or Ml.
Zinc sulfate.....	0.065
Epinephrine (1:1000).....	4.00
Zephiran chloride (1:20,000).....	30.00
One drop in each eye every three hours	

*Mydriatic Solutions*

Homatropine hydrobromide.....	2% solution	} Mydriatin or Eucadryl
Eucatropine.....	5% }	
and		
Neosynephrine.....	5% }	} Eucadryl
in methyl cellulose 1%		

*Miotics*

Eserine salicylate.....	0.25-0.5% solution
Pilocarpine hydrochloride.....	1-4 % solution
Carcholin.....	1.5% solution

*Sulfonamides*

30% sodium sulfacetamide solution; 10% ointment

*Antibiotics*

Penicillin.....	10,000 units per ml.
Terramycin (standard preparation)	
Aureomycin (standard preparation)	
Streptomycin.....	5000 10,000 units per ml.

*Other Ointments*

Zinc oxide.....	20%
Ammoniated mercury.....	1%
Atropine.....	0.5 or 1%

*To Demonstrate Denuded Areas of Cornea and Conjunctiva*

Fluorescein soluble 2% solution (this solution is easily contaminated and should be replaced frequently)

*Antiseptic Drops*

Mercuraphen.....	1:10,000
Metaphen.....	1:5000

\* All the solutions listed are now packaged sterile in plastic squeeze bottles which are not readily contaminated.

## REFRACTIVE ERRORS

### HYPEROPIA

#### (FARSIGHTEDNESS)

The hyperopic eye is shorter than normal, so that the focused image falls posterior to the retina. Only hyperopia over 4 diopters is considered abnormal in children; in hyperopia of slight degree the power of accommodation is sufficient to supplement the refracting power, but its constant use may cause headache and ocular discomfort. The total refractive error is determined under atropine cycloplegia. Refraction is indicated in children with poor vision, lack of interest in read-

ing or looking at picture books, headache, eye pain, strabismus, corneal disease, inflammations of the lid, unexplained vomiting, facial tic, torticollis or vertigo. Proper lenses provide a correction adequate for distinct vision and prevent fatigue.

## MYOPIA

### (NEARSIGHTEDNESS)

The myopic eye is longer than normal, so that the focused image falls anterior to the retina. There is poor vision for distant objects, and accommodation does not improve it. Proper lenses for full correction of the refractive error must be worn constantly, and re-examination should be performed semi-annually for the first few years and then annually. Children of myopic parents should be examined at an early age because of the hereditary tendency.

## ASTIGMATISM

In astigmatism there is a difference in the refractive power of the various meridians of the eye. The child may appear to be a careless reader because a distorted image is obtained. Symptoms include headache, eye pain, fatigue, nervousness and conjunctival irritation. Astigmatism is usually combined with myopia or hyperopia. Cylindric or spherocylindric lenses give an optical correction of the defect. Slight degrees of astigmatism often do not require any correction; moderate degrees usually require glasses for reading, movies, television, and so forth; severe degrees require that glasses be worn constantly.

Paralysis of accommodation may be due to diphtheritic paralysis of the ciliary muscle or to other neurologic conditions.

## STRUCTURAL DISTURBANCES

### ORBIT

*Exophthalmos* is a protrusion of the eyeball caused by edema, inflammation, tumor, or injury to the orbit, by enlargement of the eyeball from various causes, by dilatation of the adjoining cavities, by exophthalmic goiter, by thrombosis of the cavernous sinus and, in some cases, by paralysis of ocular muscles. Diplopia may be a prominent symptom. *Exophthalmos* produces conjunctival congestion and epiphora, and also, if it interferes with mobility of the eyeball and closure of the lids, keratitis from exposure. *Exophthalmos* may be simulated by myopia or retraction of the upper eyelid.

*Enophthalmos* is rarely encountered. Apparent enophthalmos is seen in Horner's syndrome or with ptosis from any cause.

*Retrobulbar hemorrhage* with proptosis is a rare lesion in the newborn infant.

## EYELIDS

*Ectropion* is an eversion of the lids with exposure of the conjunctival surface of the upper or lower lid. The chief symptom is epiphora resulting from eversion of the puncta. Secondarily there may be excoriations and eczema of the lower lids, redness and hypertrophy of the exposed conjunctiva and exposure keratitis. *Ectropion* may result from a cicatricial contraction following wounds, burns or operations, from chronic conjunctivitis and blepharitis, from facial palsy or spasmotic contracture of the orbicularis muscle due to acute conjunctivitis and blepharitis. If a pressure bandage does not correct it, surgery may be necessary.

*Edema of the lids* may be secondary to inflammatory, traumatic, systemic or allergic factors. It is a prominent sign in trichinosis.

*Entropion* is an inversion of the margin of the lid. The cicatricial type is due to changes in the conjunctiva and the tarsus. The spastic type is due to spasm of the palpebral portion of the orbicularis muscle and affects the lower lid. The cornea is irritated and injured mechanically. Treatment is usually surgical.

## LACRIMAL APPARATUS

*Epiphora* (watery eye) is an overflow of tears, dependent upon increased secretion from exposure, irritation of foreign bodies, or inflammation; or upon eversion of the puncta with contraction of the canaliculus, or upon plugging of the nasolacrimal duct.

## CONJUNCTIVA

*Chemosis* is edema of the bulbar conjunctiva and results from trauma, local irritation, allergic reactions or trichinosis.

*Hyperemia of the conjunctiva* is caused by local irritations such as foreign bodies, dust, exposure to bright light, acute coryza or allergy.

*Pterygium* is a triangular fold of membrane occupying the palpebral fissure and extending from the bulbar conjunctiva onto the cornea. The apex is united to the cornea and is usually blunt; the base spreads out and merges with the conjunctiva. A pterygium should be removed before the pupillary area of the cornea is involved.

*Subconjunctival hemorrhage* is manifest by

bright or dark red patches on the bulbar conjunctiva. This condition is seen after injuries, operations and inflammation of the eyeball, and in children especially after sneezing or coughing. It may be a manifestation of any of the blood dyscrasias or of scurvy. Sometimes the hemorrhage occurs without any exciting cause, and the child is unaware of its existence. It occurs relatively frequently in newborn infants. The blood is absorbed within a week or two.

*Symblepharon* is a cicatricial attachment from the conjunctiva of the lid to the eyeball, affecting usually the lower lid. It follows operation or injuries, especially burns from lye, acids or molten metals. It may interfere with motion of the eyeball and cause diplopia. The band should be separated and the raw surfaces kept from uniting again during the process of healing. Oral mucous membrane grafts may be necessary.

### CORNEA

*Kerato-ectasia* is a protrusion of the cornea following inflammation without perforation. The bulging portion is opaque. It may follow thinning from an ulcer which has not perforated or may be due to softening of the cornea after interstitial keratitis. There is always a reduction in vision.

An *opacity* of the cornea which is faint and cloudlike is termed a *nebula*; one which appears as a gray spot in daylight, a *macula*; and a dense white opacity resulting from inflammation, ulceration or injury, a *leukoma*. Reduction of the opacity may occur, but superficial keratectomy, iridectomy for an artificial pupil, or corneal transplantation may be required to improve vision. Tattooing or coloring has been used to remove the disfigurement of a leukoma.

*Staphyloma* of the cornea is a total or partially bulging cicatrix in which iris tissue is included. It is usually one of the sequels of perforation of a corneal ulcer. There is almost always increased intraocular tension; the secondary glaucoma causes pain and may lead to blindness. Iridectomy may be necessary for partial staphyloma; enucleation, for total staphyloma.

### SCLERA

*Staphyloma* of the sclera is a thinning and bulging of the sclera which may occur over the ciliary body, the equator or the posterior portion of the eyeball and is found after chronic glaucoma, iridocyclitis, scleritis or injury to the sclera. Posterior *ectasia* is a com-

mon occurrence with high myopia. If the eyeball is greatly enlarged and causes much discomfort or disfigurement and is sightless, enucleation is advisable.

### PUPIL

The *Adie syndrome* consists of one myotonic pupil, which is larger than the other one, and is often associated with the absence of reflexes or a slow contracture of the pupil to continued direct light. The pupil remains contracted for a long period after the light stimulation has been removed. The normal pupil fails to contract to 2.5 per cent mecholyl, whereas Adie's pupil does contract. The cause of the syndrome is not known; no treatment is required.

*Horner's syndrome* consists in miosis, apparent enophthalmos, narrow palpebral fissure, hyperemic cheek and an absence of facial sweating. It is usually unilateral and is due to paralysis of the sympathetic nerve supply. The pupil contracts to light and dilates with a cycloplegic.

The *retrobulbar pupillary reflex* consists in a slight constriction to light by a dilated pupil which then immediately dilates further while the light stimulation is still present. It is usually seen in patients with retrobulbar optic neuritis, which is rare in children.

### CATARACT AND DISLOCATED LENSES

A cataract is an opacity of the lens or its capsule; it may be present at birth or develop during infancy or adolescence. No symptoms accompany the formation of an uncomplicated cataract, except gradual diminution of visual acuity. The so-called complicated cataract accompanies or follows other diseases of the eye, such as iridocyclitis, choroiditis, uveitis, glaucoma or retinitis pigmentosa.

During the first two months of pregnancy, when the eye of the fetus completes most of its structural differentiation, German measles in the mother may be responsible for cataract as well as for malformations of other organs of the fetus. Affected infants often have extreme idiosyncrasy to atropine; even after one or two symptomless ocular instillations there may be considerable constitutional disturbance with fever, restlessness and, on occasion, death.

Cataracts may develop in certain metabolic disturbances such as diabetes and parathyroid insufficiency, and after the intake of certain chemical compounds such as dinitrophenol and naphthalene. Cataracts are common in

galactosemia. *Zonular (lamellar) cataract* is the most important type of developmental cataract in children. It is almost always bilateral and usually symmetrical. The opacity of the lens is evident with focal illumination as a pearly-gray, round area in the center of the lens with concentric alternating rings of clear and translucent lens substance around it. Frequently the peripheral translucent area is capped by a few radially situated opaque spokes. Ophthalmoscopically, the opaque area is black against the red reflex of the fundus.

Traumatic cataracts result from penetrating wounds or contusions of the eyeball without visible perforation, and in such instances an intraocular foreign body should be suspected. The cataract usually develops rapidly and may be complicated by secondary glaucoma. Spontaneous absorption may result, leaving a clear black pupil. More often, however, part of the lens remains opaque and requires subsequent operation.

Whether to remove a monocular congenital cataract is a moot question. It probably should be done if the cataract is extensive. Binocular cataracts which fill the pupillary area, are associated with nystagmus or cause reduction in vision below 20/50, should be removed. The age for operation depends upon visual acuity. In general, one waits as long as possible, but operation should be done early if the pupillary area is completely covered, to avoid irrevocable amblyopia.

*Dislocation of the lens* may be congenital or follow injuries to the eye, and congenital dislocation may not make its appearance until the late teens. The latter may be associated with arachnodactyly (Marfan's syndrome) and with brachymorphism (Marchesane's syndrome).

## GLAUCOMA

All congenital or juvenile glaucomas are secondary in type. The term *hydrophthalmos* is used for congenital glaucoma resulting from a defective filtration angle of the anterior chamber; *buphthalmos*, for glaucoma of any cause other than a malformed filtration angle. Both produce enlargement of the globe, but *buphthalmos* often shows clinical signs of injury or disease which are lacking in *hydrophthalmos*. There is increased intraocular pressure which causes enlargement of the eyeball, since the cornea and the sclera yield because they are not firm enough to resist stretching. One or both eyes may be involved.

The cornea is enlarged, thin, bulging and

sometimes cloudy. The anterior chamber is deep, the pupil is dilated, and the iris is atrophied. The sclera is thin and bluish, the uveal pigment showing through. Glaucoma may occur on the same side as unilateral *nevus flammeus*. The disease is usually slowly progressive to blindness, although in some cases there is spontaneous cessation of enlargement with preservation of moderately good vision. When there is persistent pain in association with blindness, the eye should be enucleated.

Goniopuncture provides subconjunctival drainage of aqueous; it has been effective in about 75 per cent of patients with *hydrophthalmos*. Early operation is advisable.

*Secondary glaucoma (buphthalmos)* develops as a result of disease, injury or operation which causes an obstruction in the flow of the aqueous. The clinical picture varies with the disease it complicates. Treatment consists in removal of the cause when possible. Surgery may be necessary to relieve the pressure, but the prognosis is not good. Enucleation is indicated if vision is irreparably lost and the eye is painful.

## STRABISMUS

(CAST, SQUINT, CROSS-EYE, WALL-EYE, TROPIA, HETEROTROPIA)

Strabismus is an imbalance of the extraocular muscles. It is of considerable importance in pediatric practice, for it often results in other problems more damaging than the functional ones of amblyopia ex anopsia (poor vision from disuse) and absence of fusion. Owing to the cosmetic blemish, psychic problems may arise. Parents should never be told to "wait and let the child outgrow crossed eyes."

Transient overconvergence or pseudostrabismus does occur, but the differential diagnosis should be the responsibility of the ophthalmologist. Infants with strabismus should be referred to the ophthalmologist by one year of age.

Many times no definite cause can be assigned. Strabismus may be congenital, and at times it seems to be familial; in some instances there are causative birth injuries; often it is first noted following an acute disease. Few people have completely "normal" muscle balance (*orthophoria*); most have a tendency for the eyes to deviate in or out, up or down (*heterophoria*). A patient with a *phoria* can keep his eyes straight by exerting effort to maintain fusion. A patient with a *tropia* is unable to fuse, and there is then an actual

visible deviation, since the visual axes are not parallel. Some children have a phoria which at times becomes a tropia (or true deviation); this accounts for the parents' story of the eyes being straight except under certain circumstances.

Fusion may be possible in some fields of gaze, but impossible in others. For example, the child may see singly when he looks straight ahead or downward, but see double when he looks upward. He therefore does all he can to avoid looking up.

Two situations may give the appearance of strabismus when it is not there, or accentuate it when it is. These are epicanthal folds and the relative position of the eyeballs in the orbit. The latter represents a disparity between the anatomic axis and the visual axis.

Though there is a wide variation in the manifestations of strabismus, there are general categories which are helpful in planning the management of each case. *Paralytic (non-comitant) strabismus* is due to paralysis of a muscle. The eyes are straight except when they are moved in the direction of the paralyzed muscle; here double vision is present. In *nonparalytic (comitant) strabismus*, which is the usual type, all the muscles are capable of rotating the eyeball as they should, but they do not work together. The two eyes are in the same relative position no matter in which direction the patient looks. Double vision is not present.

There are lateral, vertical and mixed lateral and vertical types of strabismus. Paralysis of one of the vertically acting muscles may initiate the lateral imbalance. The child sees two images, one above the other and close together. He makes every attempt to avoid double vision. He may tilt his head, close one eye or allow one eye to deviate in or out in order to get the two images together or so far apart that they do not bother him. During this transient period of double vision the child may stumble, fall, over-reach or otherwise appear awkward. He may be fussy and difficult to manage. This is the ideal time to start covering one eye, since this prevents double vision and improves appearance by hiding the deviation. The procedure makes an alternator out of what would probably be a monocular squinter, and so promotes the development of good vision in each eye.

**Methods of Testing for Strabismus.** In very young infants one can tell whether or not the eyes are straight by observing the position of the light reflexes on the corneas when a light is held before the face. Each reflex should be in the center of the

pupillary space or at corresponding points in the two corneas, such as the corneoscleral junction nasally on one eye and temporally on the other.

For older children the best test is the "screen" or "cover" test, which is carried out by having the child look at or "fixate" a small light while a narrow card is used to cover first one eye and then the other. Absolutely straight eyes (orthophoria) make no movement whatever when the card is moved. If crossing (esotropia) is present, each eye will move outward to fix on the light. If the eyes are divergent (exotropia), each eye will jump inward to fix on the light. One watches always the eye which is just being uncovered. Measurement of the amount of deviation is obtained by holding prisms base-out or base-in before the eyes during the cover test. When the proper prism is found, no movement of either eye occurs.

The ocular rotations and the ability to converge should also be tested. The nearpoint of convergence is measured by bringing a small light or pencil slowly toward the nose, asking the child to follow the light. This nearpoint should be within 10 cm. of the base of the nose. It is a good idea to touch the child's nose playfully with the light or pencil. Almost every child will smile when this is done, and co-operation is better from then on.

When the rotations are tested, one should note the relative motility with both eyes open and with each eye closed. It is useful to tell the child to "follow the light and don't let it get away."

In performing these tests it is wise to move the light *slowly* and to move the card slowly from one eye to the other. Then neither patient nor doctor becomes confused. It is surprising how much information can be gathered in a very young child with so little equipment. During such examination the parent and office nurse should not talk or move about the room: a child's attention, once distracted, may not be regained at that session.

In *amblyopia ex anopsia* or monocular strabismus one eye is deviating all the time, while the other eye is always being used. The deviating eye, not being used for definitive seeing, fails to develop good central vision. As previously noted, central vision is not developed at birth. A child with an eye which deviates ignores the image in this eye (to keep from seeing double) so that central vision does not have a chance to develop. The eye does not lose vision, and the peripheral field of vision remains normal, but the eye does not develop its potential power of seeing straight ahead.

The nonsquinting eye develops normally, and the child does not show evidence of poor vision until this eye is covered; then the disparity in vision between the two eyes is striking. Patching of the good, or fixating, eye is essential. This must be done constantly for weeks or months, and care must be taken that the improved vision does not slip when the patch is taken off.

Treatment of amblyopia ex anopsia must be

FIG. 420. Patient wearing eye patch.

carried out before the age of six years and continued until ten years if necessary. About half of the children with strabismus are amblyopic, and about one out of 150 children has amblyopia. Amblyopia should be prevented rather than treated. Good results are obtained in 80 per cent of children up to two years of age, in 60 per cent of children from two to four years, and in only 40 per cent of those from four to seven years of age.

*Alternating strabismus* is a condition in which the right eye fixes while the left eye deviates, and vice versa. Since each eye is used part of the time for definitive seeing, vision is developed equally in the two eyes, and there is no necessity for patching either eye. These children do not have double vision, since they suppress the image in the non-fixing eye. Consequently they do not have binocular vision with depth perception, but they do not miss it, since they have never had it.

*Accommodative strabismus* depends upon the relation between convergence and accommodation, both of which are controlled by the third nerve and are called upon to function at the same time. Decided hyperopia necessitates excessive accommodation with accompanying overconvergence. Myopia is likely to be associated with divergent strabismus. Accommodative esotropia disappears under cycloplegia, and correcting lenses keep the eye straight by relieving or stimulating convergence. Good vision should be maintained in both eyes, but this is not automatically done in many cases. It is, therefore, sometimes necessary to use occlusion as well as

glasses. Orthoptic treatment is often effective by developing fusion. Operation is usually deferred until the child is grown and has shown whether or not he is able to keep his eyes straight without glasses. With cautious surgical intervention a good compromise can be made between the cosmetic and functional elements.

Glasses will help, but not entirely correct, the deviation in children with convergent strabismus who have some accommodative element and whose deviation does not depend completely upon the hyperopia. It is necessary to explain to parents that glasses alone are often not enough for the correction of strabismus and that it is important not to lose time in the development of good vision in each eye. Children with partially accommodative monocular strabismus are particularly likely to develop amblyopia ex anopsia. Occlusion, to be effective, must be continuous for prescribed periods; children will cooperate when the parental attitude is proper.

*Muscle exercises* (orthoptics) are of limited value. Their greatest help is in patients with divergence and in the postoperative course of children with monocular strabismus. Orthoptic treatment of children with pure alternating strabismus is a waste of time and may be a source of nervous fatigue to the child. When properly used in selected cases, orthoptics can render great help both in overcoming amblyopia and in improving fusion ability.

*Operative treatment* is reserved for those children who do not respond to the wearing of glasses or to exercises. A high percentage of patients with strabismus, particularly convergent strabismus, eventually come to operation. It is the only successful treatment for pure alternating strabismus. Monocular strabismus of even moderate degree should be operated upon as early as possible after treatment has overcome the amblyopia. Divergent strabismus offers less cosmetic blemish, and therefore treatment is often delayed; excellent results can usually be obtained, and binocular vision developed.

**Strabismus and Cerebral Palsy.** Children with cerebral palsy may have a variety of ocular palsies and as a result may have double vision in some directions of gaze. It is desirable to do away with double vision as soon as possible, especially since many of these children have severe problems in locomotion. There are two schools of thought concerning treatment: One group advises early operation

to secure a cosmetic result; the other group, which includes the writer, recommends alternate occlusion of each eye to ensure development of equal visual acuity and to avoid diplopia. This method also takes care of the cosmetic blemish, since the patch makes the one visible eye "look straight." The muscular imbalance often becomes less marked by the time the child is five or six years of age, when, if necessary, surgical correction of residual cosmetic defects can be undertaken.

## INFECTIONS

Pyogenic and viral infections of the external eye may have their origin during birth.

### ORBIT

*Orbital cellulitis* is an inflammation of the supporting cellular tissues that may terminate in suppuration and is accompanied by great swelling of the eyelids, chemosis, exophthalmos, impairment of the motility of the eyeball, and pain which is increased by pressure. Fever and at times cerebral symptoms are present. Complications of orbital cellulitis include optic neuritis, thromboses of the retinal veins and of the cavernous sinus and, occasionally, panophthalmitis. Orbital cellulitis is usually secondary to extensive disease of the nasal accessory sinuses, especially of the ethmoids, and less often to such neighboring foci as orbital periostitis or facial erysipelas, to injuries and foreign bodies or to blood stream infection. Treatment includes bed rest, hydration, hot compresses locally, antimicrobial therapy and, if necessary, incision and drainage.

### EYELIDS

*Blepharitis* is an inflammation that involves principally the margins of the eyelids and the skin around the bases of the cilia. Redness, scales, crusts and ulcerations may be present. The lashes are often matted by cellular debris and exudate. Sometimes some of the lashes may be lost, and trichiasis may result. Seborrhea is a common cause, alone, or complicated by secondary infection. Treatment of the seborrhea of the scalp and brows is essential to the clearing of marginal blepharitis (p. 1283). Staphylococcal infections of the glands of the skin and hair follicles and of the meibomian glands are common. If response to local treatment is not prompt, determination of the organism and the antibiotic to which it is sensitive is in order.

*Hordeolum* (sty) is an infection of the follicle of an eyelash, usually caused by staphylococci. It produces redness, swelling, pain, tenderness and sometimes preauricular adenopathy. It usually goes on to suppuration and drainage. Incision should not be done, but pulling the affected cilium often results in drainage. Hot saline compresses for fifteen minutes three times a day offer the greatest help. Sties tend to occur in series.

*Chalazion* is a chronic granulomatous inflammatory involvement of a meibomian gland. The basic lesion is a reaction to fatty secretion of the gland, which acts as a foreign substance. A chalazion may start as an acute inflammation with redness and swelling, or it may develop quietly as a hard, circumscribed swelling in the tarsal plate. It may develop as a polypoid mass on the under surface of the lid. The treatment consists of hot saline compresses. Use of other local medication is usually of no avail. Absorption is much more likely to occur in children than in adults, but incision and curettage are frequently necessary.

### LACRIMAL APPARATUS

*Congenital obstruction of the nasolacrimal duct* is due to failure of canalization of the lacrimal passage. *Congenital dacryocystitis* develops when the sac becomes infected. The contents of the sac usually liquefy and become purulent. This condition should be suspected when conjunctivitis, especially unilateral, persists for several weeks. Pressure on the lacrimal sac will regurgitate fluid through either punctum, and the quality of the fluid will indicate the degree of infection present. In some instances pressure on the lacrimal sac from above will force the fluid into the nose and re-establish drainage. In some instances probing of the nasolacrimal duct to expel the epithelial plug is necessary. Acute dacryocystitis should be treated expectantly until softening occurs. Specific antibacterial therapy is advisable in the more severe infections. Probing is usually postponed until the child is six months of age, but should be done at two or three months. Probing may be done without general anesthesia if the child can be satisfactorily restrained; otherwise light general anesthesia for a few minutes is sufficient.

*Acute dacryocystitis* occurs infrequently in children without congenital obstruction of the duct.

*Dacryoadenitis* produces swelling and ten-

derness in the upper temporal portion of the orbit. It occurs with systemic infections and not infrequently with mumps.

### CONJUNCTIVA

*Acute catarrhal conjunctivitis* is common in children, but not every injected eye should be regarded as a case of conjunctivitis. Foreign bodies beneath the lid and in the cornea and uveitis may closely simulate conjunctivitis, but fail completely to respond to treatment. Most patients speak of conjunctivitis as "pink-eye," which is the epidemic form of infection by the Koch-Weeks bacillus, for which 0.2 per cent zinc sulfate solution is a specific treatment. Other causative organisms are the Pneumococcus, Streptococcus, Staphylococcus and influenza bacillus. Viral infections are common and produce little secretion, but cause tearing and preauricular adenopathy. The most common cause is infection during or after a common cold.

Treatment consists in keeping the secretion cleansed from the eye by saline irrigations, local applications of 0.5 per cent silver nitrate by the physician, and sulfonamide or antibiotic therapy. Great care should be taken to avoid local sensitivity reaction, which may prove far more distressing than the original disease. In general, one should choose an antibiotic which is not used systemically; in this way danger of sensitization is greatly decreased. In this respect solutions are better than ointments. A bland ointment will prevent agglutination of the lids during sleep. Overtreatment should be avoided, especially since most forms of conjunctivitis are self-limited.

*Inclusion blennorrhea* is a viral infection transmitted in a variety of ways, including the genital tract at birth or in swimming pools. This is one of the viral infections which are effectively treated with a sulfonamide.

*Gonorrheal conjunctivitis* (p. 303) may be acquired during birth and become evident about the third day of life, or may be acquired after birth. Although formerly an important cause of blindness, its response to several of the antibiotics and to sulfonamides is extremely rapid.

Acute conjunctivitis complicating measles responds well to 0.2 per cent zinc sulfate solution.

Conjunctivitis may be a response to drugs such as atropine, to dyes, pollens, food or other allergens. Eosinophils can be found in scrapings of the conjunctiva. Symptomatic relief can be obtained from 1:4000 epineph-

rine hydrochloride solution or various antihistaminic solutions; most of the latter cause some burning. Systemic treatment with antihistaminics is advisable if the conjunctivitis is severe.

*Vernal catarrh* is an allergic disturbance which tends to occur in warm weather and to disappear with the onset of winter. Symptoms include lacrimation, intense itching and photophobia. In the palpebral form there are hard, flattened papillae on the upper palpebral conjunctiva, producing a cobblestone appearance, and a bluish-white color of the upper and lower palpebral conjunctivas as though covered with a thin layer of milk. In the bulbar form the conjunctiva adjacent to the limbus presents gelatinous elevations, which are rarely complicated by keratitis. The conjunctiva is congested and has a stringy mucoid secretion which contains eosinophils.

The symptoms can be relieved by irrigation with saline solution or an alkaline eye wash; if there is much mucus, soothing ointments, 1:3000 epinephrine, cold compresses and the wearing of dark glasses are indicated. If a definite sensitivity to protein can be proved, the protein should be avoided or the patient desensitized to it. Carbon dioxide snow may be used to destroy the papillae. When the cornea is involved, prompt and persistent treatment must be used to avoid ulceration.

The etiologic agent of *epidemic keratoconjunctivitis* is probably a filtrable virus which is transmitted by direct contact. At first there is the sensation of a foreign body under the eyelid with moderate itching and burning. Edema of the upper lid, chemosis, and edema of the semilunar fold and the caruncle develop, and there may be pain and discomfort on rotation of the eyeball. Within forty-eight hours large, translucent, oval follicles and considerable subconjunctival infiltration develop in the lower lid, in the upper retrotarsal fold and in the fornices. The preauricular lymph nodes become slightly tender, and symptoms of upper respiratory tract infection occur, with which there is a scratchy sensation in the throat and at times follicular pharyngitis. A pseudomembrane forms on either the upper or the lower lid by the third to the fifth day. Photophobia and blurring of vision develop when corneal opacities begin as subepithelial dots. The course is self-limited without permanent loss of vision. Symptomatic relief may be obtained from cold compresses. Virus antibodies can be demonstrated in the serum after the disease has run

its course. Simple hygienic measures seem to prevent transmission.

*Trachoma* is a serious contagious inflammation of the cornea and the conjunctiva which produces pannus of the cornea and scarring of the lids. It responds to sulfonamides and to several antibiotics, so that it is becoming a less serious public health problem.

## CORNEA

*Ulcer of the cornea* begins as a dull gray infiltration of a circumscribed portion of the cornea, followed by suppuration and extension in area and in depth. Sometimes there is a tendency to heal at one site and to advance in another direction, so that the ulcer changes its situation. A small, superficial ulcer heals within a few days. The ulcer may be detected by instillation of a drop of 2 per cent sterile fluorescein, which stains green all the ulcerated portions. There is usually grayish infiltration of the cornea immediately surrounding the ulcer and considerable ciliary injection.

The symptoms are pain, photophobia, blepharospasm, lacrimation and interference with vision. When the ulcer is deep, the symptoms are more pronounced, the complications and sequels more serious, and neighboring structures are involved.

*Hypopyon* is a collection of leukocytes in the anterior chamber usually secondary to a corneal ulcer, but it may follow injury and rarely accompanies unusual types of iridocyclitis. Deep ulcers of the cornea may heal with no damage except corneal opacity, but perforation is always a serious complication. Treatment of corneal ulcers is by hot compresses, atropine, antibiotics and, if necessary, local cauterization of the ulcer.

*Phlyctenular keratoconjunctivitis* is now relatively rare, owing to the decrease of tuberculosis and to the general improvement in nutrition. The phlyctenules are accumulations of lymphoid cells beneath the epithelium of the cornea or conjunctiva. They may rupture, form ulcers and heal slowly. Cortisone applied locally results in striking but temporary relief until other measures can be instituted.

*Interstitial keratitis* is a chronic cellular infiltration of the deeper layers of the cornea without ulceration. It is associated with uveitis and leads to discoloration, clouding and vascularization of the cornea. Both eyes are usually involved. The majority of cases are due to congenital syphilis, a few to tuberculosis. It is rarely the result of acquired

syphilis, but, when it is, it is likely to be unilateral. Vision may be greatly reduced, and other symptoms include photophobia, blepharospasm, lacrimation and pain. The symptoms persist for several months, the center of the cornea being the last part to clear. When response to treatment is good, the cornea will clear completely in a year or so, or there will remain merely a faint central opacity and ghost vessels, demonstrable with the slit lamp. In all cases iridocyclitis and choroiditis occur. These untoward effects may be responsible for the visual impairment. Local treatment with hot compresses and atropine should be used with antisyphilitic treatment. Cortisone may hold the keratitis in abeyance until penicillin therapy can be effective.

In *ultraviolet burns* of the cornea the widespread loss of the superficial cells of the corneal epithelium causes exquisite pain. Treatment consists in dilatation of the pupils with homatropine or Cyclogyl, instillation of a local anesthetic (Pontocaine or Ophthaine), and covering of the eyes. Healing requires twenty-four to forty-eight hours.

## UVEA

*Iridocyclitis*, an endogenous inflammation of the iris and ciliary body, is not common in children. It occurs as a manifestation of systemic diseases, such as syphilis, tuberculosis, brucellosis and parasitic infestation, and as a response to focal infection. It may be acute or chronic. The symptoms are photophobia, lacrimation, pain in the region of the fifth nerve and diminution of vision. The signs are contracted pupil, which may be irregular in shape and may react poorly, dullness of the iris pattern and cellular precipitates on the posterior surface of the cornea. Complications are secondary glaucoma, cataract and phthisis bulbi. The treatment consists of atropine locally, hot compresses and foreign protein therapy, and treatment of the systemic disease.

*Endophthalmitis* is usually a blood-borne infection and may start as a metastatic retinitis with involvement of the vitreous and the uveal tract. It occurs with meningitis, scarlet fever, measles and subacute bacterial endocarditis. It is serious and usually leads to blindness. Nematodes have been found in excised globes. The manifestations of toxoplasmosis are most notable in the retina.

*Panophthalmitis* is an inflammation of all the structures of the eye and is frequently suppurative. It produces pain, loss of vision

and severe congestion of the eyeball, eyelids and orbit. Treatment includes symptomatic measures and the use of antibiotic agents until it is safe to enucleate the globe.

## INJURIES

Injuries to the eyes of children are common. Small abrasions and superficial foreign bodies causing acute pain prompt the parents to consult a doctor immediately. Contrariwise, injuries which do not produce pain, bleeding, sensitivity to light, or blepharospasm tend to be ignored until late. These latter injuries may be intraocular foreign bodies, traumatic iritis, perforating wounds, dislocation of the lens and detachment of the retina, all of which are of major importance. A review of the results of injuries to the eye in children indicates that they should be the responsibility of the trained ophthalmologist from the outset.

Ecchymosis and edema are signs of injury to the eyelids. Ecchymosis (black eye) is usually of no great importance except when the eyeball is involved. Blood from a basal skull fracture may appear under the bulbar conjunctiva a day or so after the injury.

*Lacerations of the eyelid* are generally more extensive than they appear externally. A small wound on the skin surface may not reflect the extent of a laceration of the tarsus. With any history of injury, prompt and complete examination of the lids, conjunctiva, cornea and sclera is necessary, even if general anesthesia is required. One or two sutures properly placed in the lid margin may obviate the necessity for extensive plastic repair at a later date, and even blindness may be avoided by prompt suturing of perforating wounds.

Perforating wounds of the globe are always of major importance, even though the eye looks white and is not painful. Even tiny perforations may be complicated by sympathetic ophthalmia.

Large lacerations of the cornea and sclera require proper appositional suturing after excision of any free uveal tissue, vitreous, and damaged lens tissue. Large wounds with escape of vitreous and hemorrhage into the eye often involve the choroid and retina. Detachment of the retina may occur. Frank infection is surprisingly infrequent. Emergency treatment should consist in instillation of a *sterile* atropine solution and application of a *sterile* pad. No ointment should be applied to the eyeball. After repair of the globe foreign protein therapy, cortisone locally and

rest in bed are indicated until the true status of the eye can be determined.

*Sympathetic ophthalmia* is a plastic inflammation of the uveal tract in one eye occurring two to eight weeks after an injury to the other eye. The signs are photophobia, lacrimation, pain in the eye and dimness of vision for close work. Examination reveals circumcorneal injection, punctate deposits upon the posterior surface of the cornea, a contracted pupil, and sometimes increased intraocular tension. Later the iris is thickened and discolored, and its markings are obliterated by extensive posterior synechiae; exudate fills the pupil; the tension is diminished; opacities develop in the vitreous, and the lens becomes opaque. Finally, the retina may be detached, and the eyeball atrophies. The pathogenesis of sympathetic ophthalmia is not understood.

The best treatment is prophylactic. Removal of the exciting eye is not the cure for sympathetic inflammation. If the exciting eye has vision, it should not be removed merely because sympathetic inflammation is present. Active treatment includes the use of atropine, hot compresses, protection from light, cortisone and injection of a foreign protein (milk or typhoid vaccine). The early use of a sulfonamide or an antibiotic may materially alter the prognosis.

An injured eye should be enucleated if it is blind and painful, if iridocyclitis persists or if a foreign body cannot be extracted. Operative treatment to improve vision should be postponed for several months after evidences of inflammation have disappeared.

Sudden onset of pain with tearing and congestion of the conjunctiva is highly suggestive of a *foreign body* on the cornea or conjunctiva. Foreign bodies can be located by examination with a condensed light and a magnifying glass. Those on the cornea may be seen best with an ophthalmoscope. Irregularities in the surface may show the location of the foreign body. The instillation of 0.5 per cent Pontocaine will facilitate examination as well as removal of the foreign body. It is wise to be sure that the anesthesia is complete and that the patient is relaxed enough to hold still. Foreign bodies should be removed with an instrument which is not sharp enough to penetrate the globe and which will lift rather than dig out the foreign body. Atropine and an antiseptic ointment should then be applied, and a sterile pad fastened securely with adhesive tape. This keeps the medication in, the patient's fingers out, and the lids closed over the cornea to promote

healing without further abrasion. If a foreign body is suspected and none is found, the eye should be examined roentgenographically.

Fluorescein in a *fresh sterile solution* should be instilled to show up any abrasion of the surface; defects in the cornea are stained green; those in the conjunctiva, yellow.

*Burns* of the eye should be irrigated and covered with a bland oil or ointment and the eye bandaged. Initially, burns from acid appear to be more severe than those from alkali, but the latter are usually more serious. In powder burns the particles, when accessible, should be removed as soon as possible by copious irrigations. Pontocaine may be used to relieve the pain. Reparative operations may be necessary after the acute stage.

*Emphysema* of the lids usually denotes a *fracture* of the wall of the orbit, permitting communication with the nasal cavity. The lids will present a soft swelling of considerable size, and on palpation there is a sensation of crepitation. A pressure bandage will hasten disappearance of the air. A fracture of the anterior wall may be detected by an unevenness of the bone. If the inner wall is involved, there may be emphysema of the orbit. When emphysema is present, rupture of the eyeball has certainly not occurred.

## TUMORS

**Eyelid.** Benign neoplasms include papillomas, hemangiomas and dermoid cysts. Non-neoplastic growths which may be found on the lids are xanthoma, molluscum contagiosum and milium. These tumors should be removed if they interfere with function or are unsightly. Malignant tumors, carcinoma and sarcoma, are rare in children; when they occur, they should be widely excised.

**Conjunctiva.** Benign tumors, which may be excised if large or unsightly, include hemangioma, nevus, lymphangioma, lipoma, dermoid cyst and papilloma. Malignant tumors which call for wide excision are melanoma, epithelioma and sarcoma.

**Cornea.** Congenital tumors are known as dermoids. A small dermoid may be confined to the limbus, but larger ones may cover the corneal area completely. Such tumors are usually easily removed, but some extend into the eye.

**Iris.** A nevus is characterized by small, excessively pigmented patches. Melanomas are rare in children. Cysts of the pigment epithelium

are benign and require no treatment. Diktyomas arise from ciliary epithelium.

**Ciliary Body.** Cysts and sarcoma are rare.

**Orbit.** Benign neoplasms and other tumors, including dermoid cyst, neurofibroma, aneurysm, meningocele and osteoma, can usually be removed with preservation of the eyeball. Malignant tumors, such as sarcoma and carcinoma, require complete exenteration of the orbit. The leukemic-like infiltration of a chloroma into the walls of the orbit is not amenable to treatment. Early metastasis to the orbit may be the first clinical sign of a neuroblastoma, manifest by exophthalmos, ecchymosis of the eyelids, and papilledema.

**Retinoblastoma.** This is a relatively rare, malignant tumor which occurs almost exclusively in infants and young children. It has its onset in utero, and in many instances a familial pattern can be demonstrated. There are two types: (1) *exophytum*, in which several pinhead-sized nodes appear in the retina and spread in the subretinal space, detaching the retina; and (2) *endophytum*, in which the tumor grows primarily toward the vitreous, the retina remaining attached to the choroid. Initially, the mass appears in the form of a small, round, yellowish-white nodule, but it is soon surrounded by small satellites which spread on the inner surface of the retina with polypoid masses extending into the vitreous. There is no pigmentation in a retinoblastoma, in contrast to that of intraocular melanomas.

In about one third of instances there are bilateral tumors, each independent of the other. There may be a period of six to twelve months before the growth is sufficient to produce such clinical manifestations as dilatation, a peculiar yellow reflex behind the pupil and defective vision. The tumor may be seen with the naked eye or with the ophthalmoscope. If secondary glaucoma develops, the eye becomes hard, congested and painful, and the cornea becomes clouded. Various types of ectasias may occur, and the sclera may perforate. Proptosis develops as the tumor forms a large, fungating, ulcerating mass which bleeds easily and bulges forward between the lids. The tumor extends by way of the optic nerve, and metastases occur by way of the blood stream, especially when the choroid has been involved by extension. These are the most important prognostic factors. Death may result relatively early from cerebral involvement by way of the optic nerve.

Differential diagnosis includes a retinal de-

tachment, metastatic retinitis, exudative retinitis and choroiditis, massive retinal fibrosis from extensive hemorrhage at birth, persistent fibrovascular sheath of the lens, or retrolental fibroplasia.

The treatment consists in early enucleation of the involved eye with removal of the largest possible portion of the optic nerve. If the tumor is bilateral, and permission for enucleation of both eyes is refused, roentgen ray therapy and triethylene melamine may be given. The local complications of roentgen therapy may be severe. The presence or absence of tumor tissue in the severed end of the optic nerve determines the prognosis. Local recurrences may develop within four to twelve months.

## RETINA

The retina may show characteristic changes associated with certain systemic diseases. In leukemia there may be hemorrhages with white centers, dilatation and tortuosity of the veins and exudation. In rare instances in the diabetic child the retinal vessels may be full and of a light color, owing to lipemia. In chronic nephritis there may be retinal edema and occasionally flame-shaped hemorrhages.

*Chorioretinitis* occurs with syphilis, tuberculosis, toxoplasmosis and septic infections. There is a reduction or loss of vision in the part of the field corresponding to the area involved. The prognosis depends upon the location of the inflammation and the response to therapy. The areas involved are at first yellowish with ill-defined margins; later there is organization leaving atrophic areas which are whitish with pigmented margins. Vitreous opacities may be associated findings. Treatment should include rest, injections of foreign protein and specific measures directed against the cause.

In amaurotic family idiocy (Tay-Sachs disease) there is a cherry-red spot at the macula surrounded by a grayish-white zone somewhat larger than the size of the disk, and optic nerve atrophy develops.

In anemia the disk and the rest of the fundus are pale, and in long-standing cases the veins are dilated and tortuous. Hemorrhages occur with severe anemia. Pulsation of the retinal arteries may be seen with aortic insufficiency. Hemorrhage of the retina may occur in association with injury in the newborn infant with such disturbances as hemophilia, purpura and cardiovascular disease and with-

out any signs of inflammation. Massive retinal fibrosis may follow hemorrhage at birth; there is a reduction in vision and sometimes detachment of the retina.

Simple *optic atrophy* is differentiated from secondary optic atrophy by the blurred margins and secondary sclerotic changes in the arterioles near the disk in the latter condition. Optic neuritis and choked disk cannot always be differentiated ophthalmoscopically, but optic neuritis has all the cardinal signs of inflammation with diminished visual function. The choked disk is noninflammatory and does not interfere with normal visual acuity until the late stages, when secondary optic atrophy develops. Intracranial lesions affecting the optic nerve in front of the chiasm usually produce diminished central visual acuity early, and there is rapidly developing simple optic atrophy. Lesions in the region of the optic chiasm produce diminished visual acuity in both eyes, but it is usually more advanced in one eye; there are pallor of the disk, simple optic atrophy, and asymmetric visual field changes, bitemporal in type. Lesions affecting the optic tract and its radiations usually produce choked disks, without interference of the central visual acuity; there are characteristic symmetric field changes of the homonymous hemianoptic type.

Posterior fossa lesions usually produce nystagmus, ataxia and rapidly developing choked disks, with no associated visual field defects.

*Detachment* of the retina is likely to occur with severe myopia, iridocyclitis, trauma or retinoblastoma. There is diminution of vision with an associated field defect. The retina is gray, the vessels dark and tortuous, and a hole or tear may be observed except in association with tumors. The prognosis is generally poor in children, but operative treatment may be effective.

*Retinitis pigmentosa* is a chronic, progressive degeneration of the retina with atrophy and pigmentary infiltration of the inner layers. There is an increasing contraction of the visual field, producing night blindness; the central region is the last to fail. There is a ring scotoma which starts typically in the equatorial region and spreads peripherally. The arteries are threadlike, the entire fundus is pale, and the disk waxy yellow; the pigmentation is in the periphery. Cataract is a frequent terminal complication. In the Laurence-Moon-Biedl syndrome retinitis pigmentosa is associated with mental retardation, hypogenitalism, obesity and polydactyly.

## RETROLENTAL FIBROPLASIA

### (RETINOPATHY OF PREMATURITY)

One of the most notable phenomena of medical history has occurred during the past sixteen years: A completely new disease of the eye has been described, studied extensively and the means for its prevention established by cooperative clinical and laboratory research.

In 1942 retrolental fibroplasia was discovered as an acquired disease in premature infants. By 1948 the nature and clinical course of the disease were understood. In 1951 the relation of intensive oxygen therapy to the occurrence of the disease was reported, and by 1955 the pathogenesis had been proved. Today retrolental fibroplasia rarely occurs.

Briefly stated, a high concentration of oxygen causes vasoconstriction of incompletely developed retinal blood vessels in the premature infant, and secondary proliferation of endothelial cells in the layer of nerve fibers in the periphery of the retina leads to formation of new vessels in the retina and in the vitreous. Detachment of the retina may follow. Regression may occur at any stage of the disease, or partial or complete blindness may result.

Prevention of this disease by giving the least amount of oxygen necessary for survival of the infant has been eminently successful. Children who were born prematurely in the past decade or so are now being seen with various degrees of myopia as a result of previously undiagnosed retrolental fibroplasia. Properly fitted glasses produce improvement in such children.

Other conditions may simulate the disease by producing a membranous structure behind the lens. These conditions are retinoblastoma, metastatic retinitis, massive retinal fibrosis, tunica vasculosa lentis, congenital cataract, effects of German measles, encephalophthalmic dysplasia, detached retina and external exudative retinitis (Coats' disease). If very marked, the fundus reflex in patients with toxoplasmosis or medullated nerve fibers may also simulate retinopathy of prematurity.

## HYGIENE OF THE EYE

Children should be encouraged to read in a good light (100 to 150 watts) which comes from behind and does not produce reflected glare. Printed matter should be held at least 14 inches from the eye. The print should not

be too small. It is wise to have the book tilted to prevent reflection from glossy paper. Good posture while reading should be encouraged.

Television is not harmful to the eyes, although it frequently brings on symptoms of fatigue and "eyestrain." The child should sit 10 to 12 feet from the screen in a room which has some general illumination. The picture should be as sharply focused as possible to reduce fatigue. The content of the programs is more important than the eye symptoms. Television, like "comics," is likely to consume too much of the interest of the child and detract from the development of good reading habits. Allowing a child to watch television while wearing a patch is sometimes effective in the treatment of amblyopia ex anopsia.

There need be no restriction of children's reading because of their refractive errors or muscle imbalances.

## SIGHT-SAVING CLASSES AND SCHOOLS FOR BLIND CHILDREN

Sight-training classes have been established in public and in private schools for children whose vision has been reduced to such an extent that they are not capable of the requirements of the ordinary school curriculum. The training consists chiefly in following the regular school curriculum by means of books printed in large type on suitable contrast backgrounds so that ocular fatigue is minimized. Special attention is given to lighting and to correct reading posture. Under this regimen children with limited but not complete loss of vision can be adequately educated.

The cooperative system for educating partially sighted children is recommended rather than placing them in schools for the blind or special schools where they are grouped with children with other abnormalities, such as deafness or cerebral palsy. Even placement in segregated classes in public schools adds its stigma. The cooperative plan places the partially seeing children with the normally seeing children in regular classrooms. Projects requiring concentrated eye work by the partially sighted children are conducted in separate, specially equipped classrooms. The psychological advantages of this plan are tremendous, just as the term "semi-sighted" is preferable to "semi-blind."

When vision has been reduced to 10/200 or less, it is almost impossible for the child to continue in sight-training classes, and he

should then be enrolled in a school for the blind. Here he is taught one of the touch systems of reading. Emphasis is placed on the teaching of manual arts and the development of a sense of independence and self-sufficiency. Those schools which teach the parents as well as the child how to handle the problem of the visually handicapped are most effective.

Children who have never had vision do not miss it and are content with the world. They should be treated as normal children and neither pitied nor rejected. Parents often regard a blind infant with awe and must be taught how to handle the situation.

# Unclassified Diseases

## AMYLOIDOSIS

This disease, uncommon in childhood, usually occurs in association with tuberculosis or chronic suppurative disease and consists in the deposition of amyloid in various tissues, especially in those of the kidney, spleen, liver, pancreas and adrenals. In recent years the incidence of the disease has declined because of the infrequent occurrence of suppurative foci.

Clinical amyloidosis usually becomes apparent within one to two years after a suppurative focus has developed; the clinical features depend on the organs involved and the degree of involvement. In *primary* amyloidosis there is no suppurative or tuberculous infection; deposition of amyloid is widespread. This type does not occur in childhood. The *secondary* type is most likely to develop as a result of caseous tuberculosis, especially in the presence of discharging sinuses. Recent reports stress the role of rheumatoid arthritis as a precursor of amyloid disease; it is estimated that between 10 and 15 per cent of patients with rheumatoid arthritis may suffer this complication. Amyloidosis should be suspected in any child with chronic disease who exhibits a gradually enlarging liver with or without splenomegaly in the early stages of the disease and without jaundice. Ascites and peripheral edema may occur late in the disease, and the skin has a peculiar waxy pallor. The urine is generally abundant and contains large amounts of albumin and waxy casts. The course is progressively downhill, and wasting is extreme. Death may occur from uremia, but in the majority of instances the original disease, rather than amyloidosis, is the cause of death.

Amyloid is principally protein in composition and has a sulfate-bearing polysaccharide fraction. It is thought to result from an allergic reaction between components of the serum globulin and certain fixed tissue elements. Amyloid is not seen within cells, but is in the intercellular tissues, which it damages by pressure or limitation of blood supply.

**Laboratory Studies.** As a result of the affinity of amyloid for various dyes, the Congo red test may prove helpful in the diagnosis of this condition. In this test (see Kolmer and Boerner) 1 cc. of 1 per cent aqueous solution of Congo red per 10 pounds of body weight is injected intravenously. Exactly four minutes later and again one hour after the injection 10 ml. of venous blood are withdrawn and the serum is separated. If possible, urine should be collected at the end of one hour after the injection and its color noted. The two specimens of serum are compared in a colorimeter, using the four-minute sample as the standard. The standard is set at 10 ml., and the one-hour sample is then read. The calculation  $\frac{\text{ml. 1-hour sample}}{\text{ml. 4-minute sample}} \times 100$

yields the percentage of dye remaining in the plasma. In normal subjects less than 40 per cent of the dye disappears from the blood in one hour. In amyloidosis 60 to 100 per cent of the dye may disappear within four minutes. If the dye is found in the urine and if there is a reduction of more than 40 per cent in the blood, the possibility of lipoid nephrosis must be considered in the differential diagnosis.

Gingival biopsy may prove helpful in the diagnosis of amyloid disease. A negative test for amyloid does not, however, exclude the diagnosis.

**Treatment.** Prophylaxis of amyloid disease is more effective today with the appropriate use of antibiotic therapy to control pyogenic infections. There is some evidence that administration of desiccated powdered whole liver is of value in treatment of the disease.

## SARCOIDOSIS

Sarcoidosis, a disease of obscure etiology, has been noted in children, although it is uncommon below the age of ten years. It has not been possible to observe this disease in a sufficiently large number of children to define the clinical pattern adequately in this age group. Most of the manifestations of sarcoidosis in preadolescent children have been extrapulmonary, whereas in adults the lesions have usually been pulmonary, with or without associated lesions in the skin, bones, eyes, and viscera.

The pathologic abnormalities noted in sarcoidosis simulate those observed in chronic granulomatous diseases, especially tuberculosis. *Mycobacterium tuberculosis* has not been demonstrated in these lesions, and most patients with sarcoidosis do not have dermal reactions to tuberculin.

The *epidemiology* is obscure. Observations made on adults in the U.S. Army have shown that Negroes are more commonly affected than white persons and that most patients, regardless of race, have come from rural communities in the southeastern United States.

Uveoparotid fever in children has been described with painless swelling of the parotid or salivary glands, fever and uveitis. Disseminated sarcoidosis involving most of the viscera has also been reported. Pulmonary involvement in the adolescent child and young adult is extremely variable in its extent and characteristics. Parenchymal infiltrates, miliary nodules and hilar and paratracheal lymphadenopathy have been observed singly or in combination in such patients.

Owing to the protean manifestations of sarcoidosis, the *differential diagnosis* is extremely broad. The diseases to be considered include tuberculosis, the various pulmonary mycoses and inflammatory ocular lesions such as phlyctenular conjunctivitis. Sarcoidosis, in adults at least, is commonly associated with hyperproteinemia and hyperglobulinemia; hypercalcemia may also be present. Multiple cystic lesions in the bones of the hands and feet have been noted in some adults. There are no specific diagnostic tests, although the Nickerson-Kveim test, consisting in formation of a granuloma several weeks after intradermal injection of material from a sarcoid lesion, is positive in the majority of active adult cases. Biopsy of affected areas is probably the most valuable diagnostic study.

*Treatment* is symptomatic and supportive. Corticosteroids cause resolution of the inflammatory ocular lesions.

The *prognosis* of sarcoidosis in children is not established, but many adults show spontaneous recovery after a prolonged illness of several months' to several years' duration.

# Neoplasms and Neoplastic-like Tissues

Cancer is one of the leading causes of death in childhood; from three to twenty years of age it is responsible for more deaths than any other disease. What appears to be an increase in the incidence of cancer in recent years is probably in large part the result of decreased mortality from other causes, especially infectious diseases. Although cancer now accounts for approximately 18 per cent of the deaths from disease in children one to fourteen years of age, it continues to be a relatively rare cause of morbidity. As a result, the experience of any physician with neoplasms in early life is likely to be limited, and their importance is often not appreciated.

*Benign tumors* are far more frequent in early life than malignant ones, and many of the benign ones represent hamartomas rather than true neoplasms.

*Hamartomas* are tumor-like congenital malformations resulting from overdevelopment of one or more tissue elements normally present at the site of the tumor, e.g., hemangiomas and osteochondromas. In general they tend to grow concomitantly with the rest of the body and thus do not exhibit the relatively uncontrolled growth characteristic of true neoplasms.

*Malignant neoplasms* have been reported in almost all sites of the body during early life. There are certain sites of predilection, however, which differ sharply from the common locations of cancer in adults. Thus the skin, gastrointestinal tract, lung, prostate and uterus are rare sites of cancer in infants and children, whereas the central nervous system, eye, renal and adrenal regions, hematopoietic system, soft tissues and bones are common sites. Sarcomas are far more common in children than are carcinomas; in adults the reverse is true. Encapsulation of a neoplasm is often considered to be indicative of benignancy in adults, but certain malignant tumors in children, e.g., Wilms' tumors, are often initially encapsulated. Increased cellularity, invasion of adjoining tissues and the presence of mitotic figures are commonly associated with cancer in adults, yet their

occurrence in hemangiomas in infants is entirely compatible with a benign clinical course. Similarly, the presence of incompletely differentiated tissues in a congenital teratoma need not be indicative of malignancy, but may merely reflect incomplete differentiation of the body tissues at this age. Conversely, the juvenile nasopharyngeal angiofibroma may be responsible for death because of its invasiveness, yet its histologic appearance may be that of an innocuous lesion.

The natural course and the therapeutic response of tumors in infants and children cannot always be predicted accurately on the basis of experience with neoplasms in adults. The clinical manifestations of malignant neoplasms in infants and children are often quite different from those encountered in adults. The rapid progression of certain neoplasms in early life may be responsible for a clinical pattern suggestive of an acute infectious process rather than a neoplastic one. In many instances, however, neoplasms in children manifest themselves as abnormal solid masses.

*Every abnormal solid mass in an infant or child should be regarded as a malignant neoplasm until its exact nature is determined by histologic examination of the removed tumor.* Needless palpation of the mass should be avoided, and complete removal should be effected after as brief a time as is consistent with adequate clinical evaluation and preparation for operation. This period usually need not exceed twenty-four to forty-eight hours. Treatment other than by surgical excision should not be instituted until an unequivocal diagnosis has been established by histologic study. Observance of these principles should prevent a number of needless deaths from cancer in infants and children.

## TUMORS OF THE NOSE, SINUSES, PHARYNX, EAR AND ORAL CAVITY

Nasal Polyps. See page 745.

*Juvenile nasopharyngeal angiofibromas* are relatively rare benign neoplasms occurring

almost exclusively in males and primarily between the ages of ten and twenty years. Nasal obstruction and epistaxis are the most frequent clinical manifestations. The tumors arise in the nasopharynx and may expand into the palate or face or invade the maxillary sinuses or orbit. Metastases do not occur, but recurrences following attempted removal or irradiation are common. The tumors are highly vascular, and bleeding may be serious or may render operative removal impossible. Although spontaneous regression may occur with sexual maturity, it is probably uncommon.

**Chordomas** (p. 1369) of the base of the skull may project into the nasopharynx, or the initial manifestations may be those of an intracranial tumor. Owing to their location, operative removal is impossible.

**Teratomas** may arise in the base of the skull, in the roof of the pharynx or in the hard or soft palate and project into the mouth, nasal cavities or cranial cavity. Some of the well differentiated teratomas projecting from the mouth have been described as parasitic fetuses and referred to as epignathi. Histologically, teratomas in this location are benign, but their location may preclude operative removal.

**Osteoma.** See page 1366.

**Papillomas** are rare benign epithelial tumors composed of irregular polypoid masses. They may be single or multiple; they arise from the nasal mucosa more often than from that of the paranasal sinuses. Clinically, they may be confused with nasal polyps. Repeated recurrences are common, and malignant transformation has been reported.

**Adenomas** are benign tumors arising from the glands of the mucous membrane of the nasal and paranasal cavities and are most frequently located in the nasal cavity and ethmoidal region; those in the latter site may erode the cribriform plate. The symptoms are related to nasal obstruction or swelling, and nasal bleeding is common. Recurrences may follow removal.

**Mixed tumors of salivary gland origin** (p. 1349) may arise in the mucous membranes of the nose, paranasal sinuses or the palate. Palatal tumors commonly arise from the posterolateral portion of the hard palate and project into the floor of the nasal cavity and maxillary sinus. The symptoms are those of nasal obstruction. Difficulty in swallowing may be noted in association with palatal tumors. The tumors may be well circumscribed and erode the adjoining bone or may be

poorly circumscribed invasive lesions. Clinical or pathologic differentiation of benign and malignant tumors may be difficult or impossible. Metastases are infrequent. Some of the tumors, especially those in which the epithelial elements predominate, may respond to irradiation.

**Benign Osteoblastoma.** See page 1366.

**Ameloblastomas.** See page 1369.

**Carcinoma of the nasopharynx** or of the tonsil may be a poorly differentiated epidermoid growth, which has been referred to as a transitional cell carcinoma or a lymphoepithelioma. A distinction between such neoplasms and lymphosarcomas arising in the lymphoid tissue of the nasopharynx may be impossible. The primary neoplasm in the nasopharynx may be a diffuse, infiltrative, nonulcerated lesion; at times it may be so small that it is overlooked, and the initial manifestation may be metastases in the cervical lymph nodes. These tumors are radio-sensitive.

**Chemodectomas (nonchromaffin paragangliomas)** are rare tumors arising in the chemoreceptor system, e.g., the carotid and aortic bodies, the ganglion nodosum of the vagus nerve and the glomus jugulare. They may arise in more than one site in an individual patient. The clinical manifestations are dependent upon the site of origin. Those arising in the glomus jugulare are manifest by the presence of an aural polyp which tends to bleed profusely and to recur, by chronic otorrhea, deafness, facial paralysis and osseous destruction in the region of the middle ear. Although the neoplasm invades adjoining tissues, metastases are infrequent.

**Nasal glioma** is a rare tumor-like mass of astrocytes, sometimes with an admixture of ganglion cells, usually found in infants. It may occur as a small subcutaneous nodule over the bridge of the nose or intranasally, where it must be differentiated from an encephalocele.

**Congenital Macroglossia.** See page 636.

**Lymphangioma of the tongue** (p. 1359) may be localized or diffuse. It may be responsible for macroglossia at birth, or a localized lesion may spread to cause macroglossia after some months or years. The lesion is usually a cavernous type of lymphangioma, and the overlying epithelium is thickened and hyperkeratotic. Multiple superficial ulcers may occur, and intermittent glossitis is a common complication. There may be associated lymphangiomatous involvement of the lip, especially the lower one. Localized

tumors are best treated by surgical excision; diffuse forms infrequently respond to irradiation.

**Hemangioma of the tongue** may be localized or diffuse. It is a less frequent cause of macroglossia than is lymphangioma, from which it may be distinguished by its deep red color and tendency to bleed.

**Neurofibroma** may be responsible for unilateral macroglossia. It usually develops before the age of three years and is often associated with neurofibromas of the skin and *café-au-lait* spots.

**Myoblastoma** is a small, superficial benign tumor composed of large granular cells, which may occur in the tongue, especially on the dorsum or along the margins. A derivation of these tumors from neural tissue rather than from skeletal muscle has been suggested. Myoblastoma of the *gum* may be present in newborn infants.

**Epulis** is a term commonly used for any tumor-like growth of the gums, many of which are probably reactive rather than neoplastic. They are pedunculated or sessile growths which may recur after simple removal, but do not metastasize. Histologically, they consist predominantly of fibrous tissue or may contain numerous multinucleated giant cells.

The **lingual thyroid** is a mass in the region of the foramen caecum at the base of the tongue which must be differentiated from a thyroglossal duct cyst. It represents residual thyroid tissue along the course of the primitive thyroglossal duct; in some instances there may be complete failure of descent of the thyroid, in which case removal of the lingual thyroid is followed by hypothyroidism.

**Embryonal rhabdomyosarcoma.** See page 1364.

## TUMORS OF THE SALIVARY GLANDS

**Mikulicz's Syndrome.** See page 638.

**Mixed tumors of salivary glands** are uncommon neoplasms in children. The parotid gland is most frequently affected, the tumor appearing as a round firm mass behind the ramus of the mandible. Histologically, various admixtures of epithelial and mesenchymal-like tissues are present, hence the term "mixed" tumor. Although metastases are infrequent, recurrences are likely.

**Mucoepidermoid tumors** of the salivary glands occur much less frequently than mixed tumors, from which they may be clinically indistinguishable.

**Hemangioma of the parotid gland** is commonly discovered at or soon after birth. It is a bluish, rapidly growing tumor which histologically may be misinterpreted as an angiosarcoma. Treatment is by prompt surgical excision.

## TUMORS OF THE NECK

**Adenomas of the thyroid** are encapsulated neoplasms which do not invade normal tissue or metastasize. They are usually solitary, but multiple adenomas may be present. Clinical and pathologic differentiation of nodular goiter from true neoplasms of the thyroid may be difficult or impossible. The presenting complaint is that of a mass in the region of the thyroid without evidence of dysfunction of the gland. Any nodule in the thyroid should be removed and examined histologically; differentiation of benign adenoma and carcinoma, however, is not always possible.

**Carcinoma of the Thyroid.** See page 1173.

**Teratomas** of the neck may be located within the thyroid or may be independent of this gland. The neoplasms are usually present at birth. They consist of solid and cystic areas containing a variety of well differentiated tissues.

**Thyroglossal Duct Cyst and Branchial Cleft Cyst; Hygroma Colli; Malignant Lymphoma.** See pages 639, 1360 and 992.

## TUMORS OF THE MEDIASTINUM

Most tumors arising in the anterior mediastinum are teratomatous or lymphomatous in origin, whereas most of those arising in the posterior mediastinum are neurogenic. They should be differentiated from cysts of the trachea and bronchi and from neuroenteric cysts and duplications of the esophagus.

## TUMORS OF THE THYMUS

**Primary malignant neoplasms** of the thymus are rare, but may arise from the lymphoid elements (lymphosarcoma) or from the epithelial elements of the organ (thymic carcinoma). The latter neoplasms are often poorly differentiated, with little or no attempt at formation of Hassell's corpuscles, and commonly contain an admixture of lymphocytes. As a result, histologic differentiation of thymic lymphoma and carcinoma may be difficult or impossible. The neoplasm surrounds and may compress the structures in the superior mediastinum, the manifestations being those of cough, dyspnea, and dilation

of the superficial veins of the head, neck and upper thorax. Roentgenographic examination reveals a mass in the anterior-superior mediastinum (p. 998). The neoplasms are usually radiosensitive. The thymus may be involved in mediastinal lymphosarcoma, leukemia or Hodgkin's disease.

**Benign thymomas** are rare neoplasms. They consist of an epithelial reticulum infiltrated with lymphocytes. Myasthenia gravis may be associated with hyperplasia of the thymus or with a benign thymoma.

#### OTHER TUMORS OF THE MEDIASTINUM

**Teratomas** are located in the anterior mediastinum, usually in its superior aspect. Many are benign cystic neoplasms, commonly referred to as *dermoid cysts*. However, since dermoid cysts appear to be merely cystic variants of the more solid teratomas, they need not be considered separate entities. Symptoms may not be apparent until adult life. Dyspnea, cyanosis and cough may be manifestations, and expectoration of hair and sebaceous material may occur if the tumor perforates into a bronchus. Infection of the cystic mass may produce symptoms simulating a pneumonic process. Rarely the neoplasm extends into the suprasternal or supraclavicular area. Compression of the superior vena cava causes dilation of the veins of the head, neck and upper thorax. Roentgenographic examination reveals a circumscribed mass extending from the anterior mediastinum into one hemithorax; when teeth or skeletal elements are demonstrable roentgenographically, the nature of the mass is established.

The neoplasms may be composed of one or more cysts; less frequently they are predominantly solid tumors. The cysts contain sebaceous material, hair or mucoid material. Histologically, almost any type of tissue may be present, especially in the solid neoplasms. Malignant teratomas are usually solid or finely cystic tumors containing actively proliferating, poorly differentiated tissue in addition to more mature elements; the malignant element may be carcinomatous, or multiple tissues within the neoplasm may behave in a malignant manner. Mediastinal teratomas should be surgically removed.

**Lymphoma, Neuroblastoma, Ganglioneuroma, Neurilemmoma, Neurofibroma.** See pages 992, 1355, 1356 and 1363.

**Cystic hygromas** (p. 1360) are usually associated with cervical hygromas.

**Mediastinal lipomas** may arise in the sub-

pleural fat and project into the pleural cavity, the cervical region or through an intercostal space. They may sometimes be identified by their radiolucency and may be suspected when there is extrathoracic extension of a mediastinal tumor.

#### TUMORS OF THE HEART

Primary tumors of the heart are rare in infants and children, and differentiation of certain benign tumors from hamartomas may be difficult or impossible. The majority of the tumors are benign, although instances of sarcoma and malignant teratoma of the heart are recorded. The diagnosis is usually not suspected during life; in a number of instances the tumors have been associated with sudden death. Diagnosis may rarely be suggested by the clinical manifestations and may be confirmed by angiocardiographic studies.

**Rhabdomyoma** of the heart is often associated with tuberous sclerosis (p. 1079). It probably represents a hamartoma rather than a true neoplasm.

**Myxomas** of the heart involve primarily the left atrium. They are usually polypoid tumors which project into the cavity of the atrium. The clinical manifestations may be those of mitral stenosis, sometimes associated with attacks of syncope and progressive cardiac failure.

**Fibroma** of the heart may be responsible for sudden death. The tumors are usually well circumscribed intramural masses, some of which may represent hamartomas rather than true neoplasms.

**Lymphangioma** of the heart may be associated with heart block. Occasionally extracardiac lymphangiomas are also present.

**Sarcomas** of various types have occurred as primary neoplasms of the heart. More than one half of these involve the right side of the heart, and involvement of the right atrium may be responsible for the superior vena caval syndrome.

#### TUMORS OF THE LUNG

Primary neoplasms of the lung are rare, although pulmonary metastases from various sites are relatively common. Every effort should be made to determine whether there is a primary extrapulmonary neoplasm whenever a pulmonary tumor is demonstrated; furthermore, removal of a suspected malignant neoplasm from any site should be pre-

ceded by roentgenographic examination of the chest in search for pulmonary metastases.

**Bronchial adenomas** are firm spherical tumors which project into the lumen of one of the larger bronchi. Ulceration of the overlying mucosa is usually a late feature. These neoplasms initially produce partial and later complete bronchial obstruction, with resultant emphysema followed by atelectasis; the initial symptoms may be those of hemoptysis, pneumonia, or bronchiectasis secondary to bronchial obstruction with retention of secretion. The neoplasm consists of cords or nests of small, round, uniform cells in a vascular stroma. Since the tumors often penetrate the bronchial wall, they should be surgically excised, even if this requires lobectomy or pneumonectomy.

**Hemangiomas** of the lung are rare and may be associated with similar lesions elsewhere. They may be demonstrated roentgenographically. Dyspnea, cyanosis, polycythemia and clubbing of the fingers and toes may be present and lead to an erroneous diagnosis of congenital heart disease. At times a bruit may be audible over the tumor. Surgical excision is the treatment of choice, but the tumors may respond to irradiation.

**Hamartomas** are usually small subpleural nodules, which only rarely reach such a size as to require surgical intervention; they are usually incidental findings at postmortem examination. Most pulmonary hamartomas have been found in adults and consist principally of cartilage.

**Adenomatoid Malformations of the Lung.** See page 781.

**Sarcoma** of the lung is rare in children; some of the reported instances probably represent metastases, and others may be posterior mediastinal neuroblastomas or undifferentiated bronchogenic carcinomas. Detailed histologic studies and careful search for an extrapulmonary source must be made before the diagnosis of primary pulmonary sarcoma can be accepted.

**Sarcomas** are massive tumors which may involve an entire lung. Cavities may occur as a result of necrosis within the neoplasm. The pleura, ribs and vertebrae may be involved, but distant metastases are infrequent.

**Bronchogenic carcinoma** is rare in children. The clinical manifestations may be those of infection, emphysema or atelectasis. Cough is usually present. Surgical excision is the treatment of choice, but the prognosis is poor.

## TUMORS OF THE GASTROINTESTINAL TRACT

**Adenomatous polyps** are usually located in the rectum and sigmoid (p. 684), but also occur elsewhere in the colon, stomach and small intestine. They are usually solitary. There may be no symptoms, or they may be responsible for abdominal pain, obstruction (especially intussusception) or hemorrhage.

**Hemangiomas of the intestine** may be diffuse infiltrating lesions with resultant thickening of the wall and narrowing of the lumen, or localized tumors projecting into the lumen of the bowel. They are at times multiple and may be associated with hemangiomas elsewhere. The manifestations are those of hemorrhage, intestinal obstruction or intussusception.

**Leiomyomas of the intestine** are rare in children; they may be responsible for intussusception.

**Carcinoids** are usually located in the appendix, less frequently in the terminal ileum, in a Meckel's diverticulum or in other parts of the gastrointestinal tract. Appendiceal tumors are often associated with obstruction of the appendiceal lumen and the clinical manifestations of acute appendicitis. Tumors of the ileum may be asymptomatic or may be responsible for intestinal obstruction. They are usually slowly growing tumors, but are probably best regarded as low grade malignant neoplasms. Metastases from appendiceal carcinoids are rare, although the muscularis and serosa are often invaded by the tumor. The higher incidence of metastases from extra-appendiceal carcinoids may be related to the later onset of symptoms with resultant delay in removal of the neoplasm.

**Lymphosarcomas** occur in the small intestine or, less frequently, in the appendix and stomach. They may be polypoid intraluminal masses or diffuse areas of infiltration of the wall of the bowel. Cures may be obtained by surgical removal.

**Multiple polyposis** is a rare, often familial condition characterized by the presence of innumerable sessile and pedunculated tumors, usually involving the colon. It should not be confused with the presence of isolated or scattered adenomatous polyps. Areas of pigmentation may be present in the mucous membranes of the lips and mouth and in the skin (Puetz-Jeghers syndrome), especially with polyposis of the small intestine. The disease may be asymptomatic or may be mani-

fest by abdominal pain, hemorrhage or intussusception. Malignant change occurs with sufficient frequency to warrant resection of the affected segment of the bowel.

### TUMORS OF THE LIVER

Metastatic neoplasms of the liver in infants and children are more frequent than primary ones, and may arise from various neoplasms, especially from a neuroblastoma. There are usually no manifestations other than hepatomegaly; in rare instances the clinical pattern of glycogen storage disease has been produced.

**Infantile hemangioendothelioma** is the usual vascular tumor of the liver in infants, cavernous hemangiomas similar to those encountered in adults being rare. The tumors are commonly multicentric within the liver, and extrahepatic hemangiomas are present in some instances. The multiplicity of the lesions and the active proliferation of vessels within them may suggest a malignant neoplasm, but they probably represent vascular hamartomas rather than true neoplasms.

Clinical manifestations are commonly present in the first weeks of life. An abdominal mass is often the only presenting complaint, but anemia and rarely ascites and jaundice may be present. In some instances cardiomegaly and evidence of congestive heart failure may lead to an erroneous diagnosis of congenital heart disease; cardiovascular manifestations have been attributed to arteriovenous shunts within the tumor. Fatal hemorrhage may occur spontaneously or after biopsy. The solitary tumors are probably best treated surgically. Multicentric tumors of the liver should be treated by irradiation, although spontaneous regression may occur in some instances.

**Adenomas** are rare solitary circumscribed neoplasms composed of hepatic cells without well defined hepatic cords. They are not associated with cirrhosis and should be differentiated from the adenomatous hyperplastic nodules associated with hepatic damage. The tumor may reach a large size and probably may undergo malignant change; differentiation from carcinoma may be difficult. They should be treated by surgical excision.

**Hamartomas** are usually solitary encapsulated tumors which may reach a large size. They are not associated with cirrhosis, and the manifestations are those of an abdominal mass. The tumor may be pedunculated or

located deep within the liver. The tumors consist of the tissues normally found within the liver, but arranged in a disorderly manner. They are not true neoplasms, but opinions differ as to whether they represent malformations or regenerative hyperplastic nodules secondary to injury. Easily resectable lesions should be surgically removed, but others are probably best left untreated after the diagnosis has been established by biopsy. There is no evidence to indicate that they become malignant.

**Mesenchymal hamartomas** of the liver are not related to the hamartomas described above. They are cystic masses which usually manifest themselves during infancy. The presenting complaint is that of an upper abdominal mass which may increase rapidly in size, owing to the accumulation of fluid within the lesion. The tumor is usually located near the lower margin of the liver. It may project into the pelvis and can often be outlined roentgenographically. The tumor can usually be identified grossly by its multicystic appearance. It is poorly demarcated from the adjoining hepatic parenchyma. Histologically, it consists of connective tissue containing cystic spaces, many of which may have no demonstrable lining cells. Small numbers of hepatic cells and bile ducts are present, especially about the periphery of the lesion. The tumor should be surgically excised, but it is probably unnecessary to sacrifice a margin of normal hepatic tissue about it, since recurrence would seem to be unlikely.

**Carcinoma** (hepatoma) of the liver, although relatively uncommon, should be considered in the differential diagnosis of an abdominal mass. The tumor may be present at birth, and in somewhat over half of the reported instances symptoms have developed before two years of age. The manifestations are usually those of gradual abdominal enlargement with the presence of a palpable mass. Pain may precede the presence of a palpable mass, and fever often occurs late in the course of the disease. Icterus and ascites are usually absent. Occasionally demineralization of the skeleton and an increase in the lipid fractions of the blood may be associated with carcinoma of the liver. Roentgen films may reveal calcification within the neoplasm. The average duration of life after the onset of symptoms is about four months.

The neoplasm may consist of a solitary mass, or multiple nodules of neoplastic tissue

may be distributed throughout the hepatic parenchyma. Cirrhosis is unusual in association with these tumors in infants and children. Histologically, they consist of closely packed hepatic cells with varying degrees of differentiation (hepatocellular carcinoma). The neoplastic cells may be well differentiated, and the lesion may thus be interpreted erroneously as a benign adenoma. Carcinoma arising from the bile ducts (cholangiocellular carcinoma) is a much less frequent type of neoplasm in children.

Small amounts of osteoid are occasionally present in hepatocellular carcinomas. In certain neoplasms, osteoid, cartilage and squamous cell carcinoma, as well as hepatocellular and cholangiocellular carcinoma, are intimately admixed with sarcomatous elements; these are referred to as *hepatic mixed tumors*. However, small amounts of osteoid are occasionally encountered in hepatocellular carcinomas, and there is no sharp line of division between these and mixed hepatic tumors.

Treatment of carcinoma of the liver consists in surgical excision. Care must be taken, however, to differentiate between nodular areas of regenerating hepatic tissue associated with cirrhosis or hepatitis and true neoplasms.

**Teratoma** of the liver is a rare tumor which is usually recognizable at or shortly after birth. They tend to have a bizarre lobated structure. They contain a variety of tissues foreign to the liver and derived from multiple germ layers, e.g., skin, brain, bone, intestinal glands.

**Mesenchymomas** of the liver are composed of a mixture of mesodermal elements, i.e., angiomatous, fibrous and undifferentiated mesenchymal tissue. Epithelial elements are usually absent. Although those occurring in the liver usually appear to be malignant, some have been successfully resected.

**Sarcoma** of the liver is rare. The neoplasms are often undifferentiated and are classified with difficulty. Embryonal rhabdomyosarcomas have been reported as arising in the liver as well as within the common bile duct.

**Ectopic adrenal tissue** may occur beneath the hepatic capsule, and rarely benign or malignant adrenal cortical tumors may arise in the liver. The diagnosis of such an *adrenal rest tumor* within the liver probably should not be made unless evidences of adrenal cortical hyperfunction are present or the hormones are identified within the tumor.

## TUMORS OF THE PANCREAS

**Adenoma of the Islets of Langerhans.** See page 1217.

**Adenocarcinomas** are extremely rare neoplasms in infants and children. The manifestations include anorexia, icterus, a palpable abdominal mass, and diarrhea; a celiac-like syndrome may occur as a result of the neoplasm. The tumor may be so undifferentiated that histologic distinction between carcinoma and sarcoma may be impossible.

**Lymphosarcoma.** (See also page 992.) Primary lymphosarcoma of the pancreas is extremely rare, but has been reported during the neonatal period.

## TUMORS OF THE KIDNEY

**Embryoma of the kidney (Wilms' tumor)** is one of the most common abdominal neoplasms of early life. The majority appear during the first four years of life; rarely it may be manifest at birth or initially in adult life. The tumor is usually unilateral. Similar neoplasms occasionally arise in the retroperitoneum independent of the kidney.

The presenting complaint is usually that of an abdominal mass. Hematuria is usually absent. Fever and leukocytosis may occur as a result of hemorrhage and necrosis within the tumor. Physical examination reveals a firm, nontender mass, which may extend to the midline and down into the iliac fossa; it does not commonly cross the midline as a neuroblastoma is likely to do. Pyelography reveals no characteristic pattern, but distortion of the renal pelvis is common; lateral displacement of the affected kidney is less likely than with a neuroblastoma. Although such features may strongly suggest that the mass is a Wilms' tumor, no pathognomonic signs exist; an unequivocal diagnosis is established only by histologic examination.

Macroscopically, the neoplasm is encapsulated until a relatively late stage, when it may invade the renal pelvis and ureter, renal veins or perirenal fat (Fig. 421). The capsule of the tumor is continuous with that of the affected kidney, and subcapsular hemorrhage may be responsible for pain or for apparent rapid "growth" of the neoplasm. The regional lymph nodes and the lungs are common sites of metastases.

Histologic examination reveals a somewhat varied pattern in different neoplasms and in different parts of the same tumor. The most

FIG. 421. Wilms' tumor in lower portion of right kidney. The kidney and tumor have been hemisected.

common appearance is that of broad cords and sheets of undifferentiated mesenchymal cells separated from each other by loose connective tissue, and containing tubules in varying stages of differentiation; this sarcomatous and carcinomatous pattern has given rise to the terms "adenosarcoma" and "mixed tumor of the kidney." Other structures may also be present, which include abortive glomeruli, skeletal and smooth muscle fibers, squamous epithelium and cartilage. Since all these elements are readily derived from mesenchymal tissue, these neoplasms should not be regarded as teratomas.

When a persistent abdominal mass which *could* be a retroperitoneal neoplasm is present, surgical exploration is indicated. Preliminary studies should be conducted promptly (twenty-four to forty-eight hours) and with as little trauma as possible; unnecessary palpation of the tumor should be avoided. Pyelography is indicated to determine the location of the mass, if possible its nature, and in particular to demonstrate that the opposite kidney is functioning adequately. The surgeon should be prepared to remove the mass or to perform other appropriate measures, e.g., drainage and/or plastic repair of a hydronephrosis. Preoperative roentgenograms of the chest should be made in an attempt

to exclude the presence of pulmonary metastases.

Although cures of Wilms' tumors may occur after irradiation alone, histologic examination of tumors removed after a course of roentgen therapy commonly reveals neoplastic cells. Preoperative irradiation is generally contraindicated, since by such treatment of occasional benign or non-neoplastic lesions may be needlessly irradiated, with injurious sequelae. During the operative procedure ligation of the renal veins and ureter prior to manipulation of the mass is important in preventing spread of the neoplasm by these routes. The perirenal fat and any regional lymph nodes encountered should be removed. Postoperative irradiation to the site of the neoplasm is currently used, even though there is evidence to suggest that permanent damage to the opposite kidney may rarely be produced.

The prognosis of Wilms' tumors, although grave, is not as hopeless as formerly considered. In recent years the experience in certain medical centers has been highly encouraging; in one reported series apparent cures were obtained in 47 per cent of the entire group, and 80 per cent of the infants less than twelve months of age survived two years or longer. The accumulated data of Abeshouse from a rather large number of sources disclose a survival rate of only 20 per cent two years after removal of the tumor; at ten years only 5 per cent had survived. Late recurrences or metastases are less common in infants than in older children. If recurrences or metastases have not occurred after a period equivalent to that of the age of the patient at the time of removal of the neoplasm plus nine months, the probability of cure is good. However, Abeshouse records deaths from the neoplasm as long as twenty years after removal of the primary tumor. It is difficult, however, to be as pessimistic as this last report would appear to justify, in view of the much better results which have been obtained in centers where there is considerable interest in this problem as compared with the general experience throughout the country.

**Hypernephroma (renal cell carcinoma),** the common renal carcinoma in adults, is extremely rare in children.

**Adenomas** or small benign growths composed of epithelial elements may occur in association with angiomas of the retina and cerebellum and with cysts of the pancreas and kidney (*I Lindau's disease*); they probably are hamartomas rather than true neoplasms.

**Hamartomas** or small fibrous nodules may occur in the renal medulla or less frequently in the cortex; they are not sharply limited and may contain tubules as well as connective tissue, smooth muscle and fat.

Multiple tumors of varied histologic structure may be present in each kidney in patients with *tuberous sclerosis* (p. 1079); rarely renal insufficiency may occur as a result of these tumors.

## TUMORS OF THE ADRENAL

**Neuroblastoma** is one of the most common malignant neoplasms in infants and children. Although commonly arising in the adrenal medulla or periadrenal tissue, it may arise at any site along the sympathetic chain, e.g., the retroperitoneum, posterior mediastinum or the cervical ganglia. The majority occur in the first three years of life and may even be widely disseminated at birth. Bilateral involvement of the adrenal glands may occur. The presenting complaint is commonly that of an abdominal mass, but at times the primary tumor is small, and the initial complaints are referable to metastatic lesions, e.g., pain in the extremities as a result of osseous metastases, exophthalmos from orbital metastases, or massive hepatic enlargement. Fever and leukocytosis may be present, and the clinical manifestations may suggest an infectious rather than a neoplastic process.

A neuroblastoma in the adrenal or periadrenal region often crosses the midline, in contrast to a Wilms' tumor. Roentgenographic examination commonly reveals lateral and downward displacement of the kidney on the affected side; focal areas of calcification are more often present in neuroblastoma than in Wilms' tumor, and distortion of the renal pelvis is more common in the latter neoplasm. However, intrarenal neuroblastomas may occur and be macroscopically indistinguishable from Wilms' tumor.

The tumor is initially encapsulated, but later may extensively infiltrate the surrounding tissues. The aorta, inferior vena cava, ureter and renal pedicle may be completely surrounded by neoplasm, making complete surgical excision impossible. Removal may also be impaired by extensive areas of hemorrhage and necrosis within the tumor. Metastases are often widespread, common sites of involvement being the liver, bones, orbits, meninges and lymph nodes. The osseous metastases may be extensive, and aspiration of bone marrow may reveal characteristic

pseudorosettes even in the absence of roentgenographic changes. Roentgenograms of the skeleton often reveal widespread destructive lesions of many bones, with multiple areas of rarefaction (Fig. 422). In the long bones the destructive process and associated periosteal reaction may simulate the appearance of osteogenic sarcoma or, more frequently, of Ewing's tumor (Fig. 425) or of acute leukemia; bilateral symmetrical involvement of

FIG. 422. Roentgenograms revealing metastatic neuroblastoma involving the tibias and tarsal and metatarsal bones. Note the tendency toward a symmetrical distribution of the lesions. Extensive periosteal new bone formation is present in the right tibia; the appearance simulates that of a primary neoplasm of bone.

the long bones and pelvis is often present. Ewing's tumor (p. 1368) and the osseous metastases of neuroblastoma may also be similar histologically, and every attempt should be made to exclude the latter before accepting a diagnosis of Ewing's tumor.

The neuroblastoma may show varying degrees of differentiation toward mature ganglion cells, or rarely toward mature chromaffin tissue. The more undifferentiated neoplasms, in which pseudorosettes are not apparent, may be misinterpreted as malignant lymphomas. Better differentiated areas reveal the classic pseudorosettes or, less frequently, immature or mature ganglion cells. However, all grades of differentiation may be present in a single neoplasm, and examination of multiple sections may be necessary before the neuroblastic nature of the lesion can be established. Many have been erroneously referred to as lymphosarcoma or undifferentiated sarcoma.

The diagnostic study of a patient suspected of having a neuroblastoma is similar to that described under Wilms' tumor. Roentgenograms of the skeleton and chest and a pyelogram should be obtained. Examination of material aspirated from the bone marrow may aid in establishing the diagnosis.

*Treatment* consists in surgical removal of the primary neoplasm, followed by irradiation of the operative site; if complete surgical excision is impossible, removal of as much of the neoplasm as can safely be performed should be attempted. Some systemic antineoplastic agent such as Aminopterin, nitrogen mustard or a corticosteroid is used as an adjuvant in our clinic. Localized metastases which are apparent initially or appear later and which are not readily removable surgically are treated with roentgen irradiation. A number of recoveries after hepatic metastases and even a few after localized skeletal metastases are recorded.

Spontaneous cures of neuroblastoma are extremely rare. In recent years recoveries following therapy have been reported with increasing frequency and certainly justify treatment of any patient who is not in a terminal condition. The results of therapy are probably dependent upon the age of the patient as well as upon the stage to which the disease has advanced at the time therapy is instituted; the prognosis is definitely better in infants than in older children.

**Ganglioneuromas** are composed of ganglion cells, Schwann cells and neurites and

are apt to occur at a slightly older age than are neuroblastomas; the majority are found before the age of twenty years. They arise from the sympathetic ganglia in the retroperitoneum, posterior mediastinum, cervical region or adrenal medulla or rarely from ganglia in other locations. The tumors are encapsulated and often attain a large size before clinical manifestations appear. They are usually solid tumors without the extensive areas of hemorrhage or necrosis common in the neuroblastoma. Completely differentiated ganglioneuromas are benign neoplasms; the less differentiated forms, however, contain immature ganglion cells or neuroblasts and may metastasize. Many sections of these neoplasms should be examined histologically in order that less differentiated areas may not be overlooked.

**Pheochromocytoma; Adrenal Cortical Tumors.** See pages 1192 and 1189.

## OTHER RETROPERITONEAL TUMORS

**Retroperitoneal teratomas** are the third most frequent type of retroperitoneal neoplasm in infants and children, neuroblastoma and Wilms' tumor being more common. Approximately half of retroperitoneal teratomas are found during the first year of life. They are usually large tumors arising high in the retroperitoneal region; they may occupy one side of the abdomen or cross the midline. The presenting complaint is usually that of an abdominal mass; many of the masses show no apparent growth over a period of several months. Roentgenographic examination often reveals areas of mineralization within the tumor, in addition to displacement of the kidney or ureter. Clinical differentiation of the teratoma from neuroblastoma or Wilms' tumor may be impossible. Prompt surgical removal preceded by pyelograms and roentgenograms of the chest and skeleton is the treatment of choice.

**Pelvic and retroperitoneal teratomas** are large tumors arising in the presacral region. They extend upward into the retroperitoneal tissues and may extend outward into the buttock.

**Sacrococcygeal Teratoma; Chordoma.** See pages 685 and 1369.

**Tumors of the soft tissues of the retroperitoneum** (p. 1362) include benign and malignant tumors derived from adipose or fibrous tissue and malignant tumors derived from skeletal muscle. They are usually bulky

neoplasms which clinically may be indistinguishable from the more common retroperitoneal neoplasms: Wilms' tumor, neuroblastoma and teratoma.

**Retroperitoneal lipoma; retroperitoneal lymphoma.** See pages 1362 and 992.

**Retroperitoneal lymphangiomas** are large cystic tumors composed of dilated lymphatics, which may occur independently or in conjunction with similar tumors in the mesentery.

**Retroperitoneal hemangiopericytoma.** See page 1359.

## TUMORS OF THE BLADDER AND PROSTATE

Neoplasms of the bladder are rare. The majority are rhabdomyosarcomas, although leiomyosarcomas, myxomas, papillary carcinomas of low grade malignancy and hemangiomas have been reported.

Rhabdomyosarcomas (p. 1364) may originate in the bladder or prostate. They usually occur in the first decade and have been reported at birth. They are bulky masses, often with a grapelike configuration (sarcoma botryoides) and usually can be palpated through the rectum. Clinically they are manifest by obstruction to the flow of urine, hydro-nephrosis with secondary pyelonephritis, frequency, dysuria and hematuria. Metastases are usually relatively late, but early extension to contiguous structures is common. The prognosis is extremely grave. Radical surgical extirpation is the treatment of choice, possibly followed by irradiation.

## TUMORS OF THE TESTIS

The highest incidence of testicular neoplasms in early life is during the first three years. The majority of the tumors are malignant, embryonal carcinoma being the most common type; seminomas are extremely rare in infants and children. The presenting complaint is usually that of painless swelling of one testis. The tumor is firm, cannot be transilluminated, and the overlying skin is often discolored, but not adherent to the mass. In some instances the initial complaint is that of a palpable abdominal mass, the result of metastases from an unrecognized testicular neoplasm.

**Embryonal carcinoma** is the most frequent type of testicular neoplasm in infants and children. Metastases are especially likely to be located in the iliac and periaortic lymph

nodes and lungs; involvement of the left supraclavicular lymph nodes may follow intrathoracic metastases. The prognosis is grave, but cures have been obtained.

**Teratomas** contain various tissues derived from different germ layers and may consist of both fetal and adult structures. They are all considered malignant tumors, since in large series in adults there has been no relation between the clinical behavior and the apparent differentiation of the elements within the tumor. Teratomas may contain admixtures of other germinal tumors, i.e., seminoma, embryonal carcinoma or choriocarcinoma.

**Seminomas** consist of sheets of rather uniform cells separated by trabeculae of connective tissue in which lymphocytes are often present. The prognosis is better than that associated with the other malignant testicular neoplasms.

**Testicular choriocarcinomas** are neoplasms containing villous-like arrangements of cytotrophoblasts and syncytial trophoblasts. Pure choriocarcinomas are less frequent than are choriocarcinomatous foci in other testicular neoplasms, especially in embryonal carcinomas and teratomas. Gynecomastia and urinary chorionic gonadotropin may be present in association with choriocarcinoma, but may also occur with embryonal carcinomas.

**Testicular adenocarcinoma with clear cells** has been described as a distinctive type of neoplasm of infants. It is a locally invasive tumor which may metastasize, but cures have occurred after orchiectomy and postoperative irradiation. The cell of origin of the neoplasm is not established.

**Androblastomas** are rare testicular tumors comparable to ovarian arrhenoblastomas (p. 1358). They may be present at birth.

*Treatment of neoplasms of the testis* consists in orchiectomy preceded by ligation of the spermatic cord as high as possible. Adjuvant therapy is dependent upon the type of neoplasm, but it should be recognized that different types of neoplastic cells may occur within a single tumor. Seminomas, which are highly radiosensitive, are probably best treated by orchiectomy followed by irradiation to the entire periaortic chain of lymph nodes as well as to the left supraclavicular lymph nodes. Embryonal carcinoma and choriocarcinoma are less radiosensitive and are best treated by orchiectomy and resection of the iliac and periaortic lymph nodes to the level of the renal pedicles, followed by irradiation. A

similar operative procedure should be performed for teratomas, but the value of postoperative irradiation in these tumors is questionable.

**Interstitial Cell Tumor.** See page 1197.

## TUMORS OF THE OVARY

Ovarian neoplasms in infants and children are rare. The manifestations are usually pain and an abdominal mass; torsion of the pedicle may be associated with nausea and vomiting, the clinical findings suggesting a diagnosis of acute appendicitis.

**Teratomas of the ovary** may be cystic benign tumors (dermoid cyst) or predominantly solid neoplasms, the former being somewhat more common. Over half of the solid teratomas in children are responsible for death. Ovarian teratomas are usually unilateral and are palpable through the abdominal wall or by rectal examination. Roentgenograms may reveal areas of calcification within the mass. Rarely isosexual puberty may occur in association with choriocarcinomatous elements in a teratoma of the ovary. *Treatment* is by surgical excision.

**Cystadenomas of the ovary** are less frequent than teratomas. They are usually unilateral and benign. They may be serous or pseudomucinous. Simple cysts probably represent non-neoplastic follicular cysts or unilocular serous cystadenomas. Treatment consists in surgical excision.

**Carcinomas of the ovary** in children are usually solid unilateral tumors which are initially encapsulated. They should be treated by surgical excision; the value of postoperative irradiation is questionable.

**Dysgerminomas** are probably derived from undifferentiated cells which have not yet developed male or female characteristics. They occur predominantly after the age of ten years. There may be associated genital hypoplasia or pseudohermaphrodis, but the neoplasm does not secrete hormones. More than one fourth of the tumors are bilateral. They are solid tumors, often with areas of hemorrhage and necrosis; histologically they resemble seminomas of the testis. The tumor is radiosensitive and is probably best treated by surgical excision and postoperative irradiation.

**Arrhenoblastomas** are masculinizing tumors of the ovary occurring principally in adults; they have been observed in adolescent girls, but not in prepuberal children.

**Granulosa Cell Tumor.** See page 1201.

## TUMORS OF THE VAGINA AND UTERUS

**Sarcoma botryoides** is a descriptive term referring to a polypoid, grapelike malignant neoplasm of mesenchymal origin. They are predominantly embryonal rhabdomyosarcoma (p. 1364), but those arising from the vaginal wall or cervix uteri and projecting into the vagina or externally through the vulva may also contain areas of cartilage or other mesodermal elements. They frequently invade the bladder, and determination of the site of origin may be impossible. They are most frequent in the first few years of life. The manifestations are urinary frequency, bloody or profuse foul-smelling vaginal discharge and the presence of multiple polypoid "grapelike," edematous or hemorrhagic masses protruding into the vagina. Metastases may occur to the lungs and other viscera as well as to lymph nodes. The prognosis is extremely grave. They should be treated by radical surgical excision, including hysterectomy and possibly postoperative irradiation.

## TUMORS OF THE SKIN AND SOFT TISSUES

**Hemangiomas** are probably congenital malformations (hamartomas) rather than true neoplasms, but they may exhibit various neoplastic qualities. They are the most common tumors in infants and children, the majority being present at birth or developing within the first year of life. With rare exceptions the tumors are benign, and treatment is largely for cosmetic purposes.

**Capillary hemangiomas (strawberry nevi)** are well circumscribed, slightly elevated, bright red to deep purple tumors which incompletely blanch on pressure. They consist of multiple lobules of small capillaries interspersed with cords of cells resembling endothelium, but without distinct vascular lumens. *Hemangioendotheliomas* are probably only variants of the capillary hemangioma in which the predominant pattern is that of endothelial proliferation with sparsely developed vascular lumens. Hemangiomas, especially in infants, may reveal active cellular proliferation with scattered mitotic figures and invasion of surrounding tissues or even of veins; in spite of such histologic findings they almost always behave clinically as benign tumors. They may be treated by application of carbon dioxide snow or dry ice, irradiation or surgical excision (p. 1274), but in the majority of instances they will spontaneously regress over a period of a few years. Accord

ingly, unless they are in a location where they interfere with function, they are probably best not treated.

**Cavernous hemangiomas** are poorly circumscribed, blue or purple elevated tumors which tend to extend more deeply into the subcutaneous tissues than do the capillary hemangiomas. They consist of numerous cystic vascular spaces containing blood. Mixed forms of cavernous and capillary hemangiomas are common. Cavernous elements which do not regress spontaneously are probably best treated by surgical excision. Cavernous hemangiomas may occur in sites other than the skin, e.g., in bone, liver and in the tongue. In skeletal muscles they manifest themselves by pain and the presence of a diffuse mass which decreases in size with elevation of the part; foci of calcification may be demonstrable by roentgenographic examination. Hemangiomas of the intestine, which may be capillary or cavernous, may be responsible for hemorrhage and intussusception. *Diffuse hemangiomas* of an extremity may be associated with hypertrophy of the part and of the associated bone. Rarely large vascular tumors may be associated with thrombocytopenia, purpura and anemia.

**Nevus vinosus** (*nevus flammeus*, *portwine mark*) is usually located on one side of the face and may correspond to the distribution of the trigeminal nerve. It is a flat, irregular lesion which may be light pink at birth and later deep purple. It blanches on pressure. It consists of scattered dilated vessels in the superficial dermis. Treatment is unsatisfactory. A somewhat similar lesion is often present in the nape of the neck, over the bridge of the nose or on the eyelids of newborn infants; these usually disappear spontaneously.

**Cirroid aneurysms** (*racemose hemangioma*, *congenital arteriovenous fistula*) are rare lesions consisting of a pulsating mass of dilated, tortuous arteries, veins and capillaries. They may be associated with a nevus vinosus.

**Glomus tumor** is a small bluish tumor usually located on the extremities, especially in the subungual region. It manifests itself by excruciating pain, especially on contact. Histologically it resembles a cavernous hemangioma except for the presence of discrete glomus cells in the walls of the vessels. The tumor is benign, and treatment is by surgical excision. Such tumors are rare in children.

**Hemangiopericytomas** are rare tumors thought to be derived from cells normally

located just outside the basement membrane of the capillaries. The tumor may occur in the superficial soft tissues or in deeper tissues, e.g., the retroperitoneum. The vascularity of the tumor may not be apparent in routine histologic sections. The malignancy of the tumor varies and often cannot be correlated with its histologic pattern; congenital hemangiopericytomas are usually benign.

**Hereditary hemorrhagic telangiectasia** (*Rendu-Osler-Weber disease*) consists of multiple minute reddish-purple spots composed of thin-walled dilated capillaries and venules, occurring most frequently in the mucous membranes of the nose and mouth, but at times in the skin and in various viscera. There is a history of repeated hemorrhages, especially epistaxis, and of familial occurrence. Recurrent attacks of epistaxis may begin during childhood and may precede the appearance of the telangiectases.

**Angiomas of the retina** (*von Hippel's disease*) may be associated with cerebellar angiomas, cysts of the pancreas and adenomas of the kidney (*Lindau's disease*).

**Sturge-Weber syndrome.** See page 1080.

**Lymphangiomas**, which are less common than hemangiomas, are also probably malformations (hamartomas) rather than true neoplasms. They are often present at birth. The most common locations are on the neck and extremities. The various types of lymphangioma may be associated with each other in a given tumor, and other mesodermal elements, including smooth muscle, adipose tissue, foci of lymphocytes and hemangiomatous areas, may also be present. The tumors are benign, but, because of their infiltrative tendency, recurrences are common, and complete surgical extirpation may be difficult or impossible.

**Simple lymphangiomas** are rare, small, flat or verrucous lesions usually located on the face or neck. They consist of dilated lymphatic vessels in the superficial dermis.

**LYMPHANGIOMA CIRCUMSCRIPTUM** is a rare condition characterized by the presence of small groups of thick-walled vesicles. It may be present at birth or begin in infancy or childhood. The lesions are superficial simple lymphangiomas.

Diffuse lymphangiomas are poorly circumscribed tumors occurring in the skin, mucous membranes or muscles. They are usually congenital. In the tongue and lips they are responsible for macroglossia and macrocheilia, respectively. Diffuse lymphangioma of an extremity is responsible for one form of

FIG. 423. A, Three-year-old girl with large multicystic cystic hygroma of the mesentery (mesenteric cyst). B, The cyst with its contents weighed almost 4000 gm.

elephantiasis (*elephantiasis lymphangiectatica*). It may involve an entire extremity or only a portion, e.g., the fingers or foot; there may be associated hypertrophy of the bone in the affected area. Histologically, the dilated lymphatic channels may be obscured by abundant scar tissue. The more localized lesions should be treated by surgical excision, but recurrences are frequent. Treatment of the more diffuse lesions is usually unsatisfactory; lymphangiomatous macroglossia may respond to irradiation.

**Cystic lymphangiomas (cystic hygromas)** are most frequently encountered in the neck (hygroma colli) and in the axillae, but may also occur in the inguinal and retroperitoneal regions. In the cervical region they may extend into the mediastinum, and rarely mediastinal hygromas may occur in the absence of a cervical component. *Omental* and *mesenteric* cysts (Fig. 423) are frequently cystic hygromas. *Sacral hygromas* may simulate lipomas or sacrococcygeal teratomas; they are sometimes connected with the spinal canal. Enlargement of cystic lymphangiomas may occur as the result of enlargement of the individual cysts, from the formation of new cysts or from hemorrhage into the cysts.

**HYGROMA COLLI** is the most common type of cystic lymphangioma. It is usually

demonstrable at birth as a soft, poorly defined mass, often in the posterior cervical triangle; many of the tumors can be transilluminated. Periodic fluctuations in the size of the mass are common, and rapid increase in size is often associated with hemorrhage into the cystic spaces. The size of the cervical component of a cervicomedial hygroma is greatly influenced by crying or by the phase of respiration. The tumors are often asymptomatic, but respiratory difficulty or difficulty in swallowing may occur with severe displacement of the trachea or esophagus.

The tumor may surround vessels and nerves, and the cystic spaces may project in various planes, making surgical excision difficult. They are lobulated, thin-walled cystic structures which are usually multilocular; the cystic cavities may be independent of one another or may communicate freely. The contents usually consist of clear colorless fluid, but this may be xanthochromic or bloody. The walls of the cysts are lined by endothelium and are composed of connective tissue, smooth muscle and foci of lymphocytes.

Cystic lymphangiomas should be treated not only for cosmetic purposes, but also to prevent complications such as infection and mediastinal compression. Hygroma colli and

ygromas of the mediastinum are best treated by surgical excision. Irradiation is sometimes used for tumors which are not surgically accessible, but in general the tumors are not susceptible to radiotherapy.

**Epidermoid cysts** are spherical, benign tumors often located in the skin of the neck, face or scalp; they are probably derived from congenital ectodermal rests and are not true neoplasms.

Epidermoid cysts in the calvarium are demonstrable roentgenographically as sharply demarcated defects surrounded by dense sclerotic bone.

**Dermoid cysts** are clinically indistinguishable from epidermoid cysts and probably have similar derivation; they should not be interpreted as teratomas. They are often located in the skin above the eye. Histologically they resemble epidermoid cysts except for the presence of skin appendages in their walls.

**Calcifying epitheliomas** are hard, sharply demarcated benign tumors of the skin which may arise at any site, especially in the face or upper extremities. Clinically they may be confused with epidermoid cysts, and pathologically they have been interpreted by some as representing proliferative and secondary degenerative changes in an epidermoid cyst. Their principal importance is the fact that histologically they may be interpreted erroneously as carcinoma.

**Pigmented nevi** in infants and children are usually clinically benign, even though their histologic appearance may simulate that of the malignant melanoma of adults. They may be present at birth as large, rough, dark brown or black areas, as in the "bathing trunk" nevus, sometimes with smaller nevi in the surrounding skin. Smaller nevi may first be noted in infancy, childhood or even adult life. The tumors may be located at almost any site, may be smooth or papillary, light brown to almost black, and may contain hair.

The histologic pattern of nevi in infants and children varies somewhat from that usually encountered in adults. Benign nevi in children tend to be more cellular than those in adults, are more likely to have multinucleated cells and may contain mitotic figures. Failure to recognize the occurrence of these features in the benign nevi of infants and children may lead to an erroneous diagnosis of malignant melanoma.

Certain nevi reveal an even more striking histologic similarity to that of the malignant

melanoma of adults and have been referred to as *juvenile melanomas*. They tend to be somewhat larger, purplish red rather than dark brown, hairless, and somewhat more elevated than the usual nevi in children. They are benign lesions which should be treated by conservative surgical measures.

Owing to their frequency, removal of all nevi is not feasible. Those on the genitals, palms of the hands and soles of the feet as well as those in other sites which are subjected to repeated irritation should be removed prior to puberty. The occurrence of increasing pigmentation, ulceration, rapid growth or a pigmented halo about a nevus is an indication for surgical excision of the growth with a wide margin of intact skin.

**Malignant melanomas** are rare prior to puberty. Histologically, they resemble the more active malignant melanomas of adults. They may occur in association with xeroderma pigmentosum. Malignant melanoma in the pregnant woman has been reported as metastasizing to the placenta and infant.

**Blue nevi** are usually smooth, firm, blue or bluish black nodules occurring on the face, buttocks, or dorsum of the feet or hands. The lesion may resemble a mongolian spot histologically, and cellular forms have been misinterpreted as malignant. Malignant transformation of a blue nevus, however, is rare.

**Dermatofibrosarcoma protuberans** is a slowly growing invasive tumor arising in the dermis. It begins as one or more hard, painless nodules which slowly coalesce, protrude from the skin and may ulcerate. The fibroblastic tissue within the neoplasm tends to form irregular strands and whorls. The tumor may recur locally over a period of many years, but metastases are rare.

#### TUMORS OF SKIN APPENDAGE ORIGIN

The classification of neoplasms derived from skin appendage is not entirely uniform, and differentiation between neoplastic and non-neoplastic lesions may be difficult. The tumors tend to be clinically benign, although in some the histologic pattern may suggest a malignant neoplasm. Only a few of the tumors of skin appendage origin will be discussed.

**Syringocystadenoma papilliferans** is a tumor derived from the ducts of apocrine glands. It usually occurs as a single plaque, most frequently on the scalp; minute cysts are sometimes visible within the lesion, the surface of which may reveal areas of crust-

ing. Histologically it consists of numerous villous-like processes which project into the lumens of the dilated ducts.

**Syringomas** occur as hundreds of small, soft, slightly elevated, yellowish pinhead-sized nodules, especially about the eyelids, chest, abdomen and anterior aspects of the thighs. They are found predominantly in females and develop at the time of puberty. Histologically they consist of numerous small cystic ducts located in the dermis. These are benign lesions which are probably not true neoplasms.

**Tricho-epithelioma** (epithelioma adenoides cysticum) usually occurs in females at the time of puberty. It is frequently familial. Multiple small discrete yellow to pink nodules appear on the face and occasionally on the upper trunk. The tumor is derived from hair follicles and may contain areas closely simulating basal cell carcinoma; rarely a basal cell carcinoma may develop in adult life.

**Cylindromas** (turban tumors) are multiple benign growths which are often familial. They occur predominantly on the scalp of females, sometimes appearing in early childhood or at puberty. They usually appear initially on the forehead as smooth, firm, freely movable, painless nodules. They increase in number and size throughout life, so that ultimately the entire scalp may be covered by a lobulated mass of lesions. The origin of these tumors is disputed. They are nearly always benign and are best treated by surgical excision.

**Nevus sebaceus** (Jadassohn) is a circumscribed, slightly raised firm yellow plaque usually occurring on the scalp or face and present at birth. It is composed of large numbers of sebaceous glands.

**Adenoma sebaceum** (Pringle). See pages 1079, 1139 and 1280.

#### **SQUAMOUS CELL CARCINOMA; BASAL CELL CARCINOMA**

These are rare in children, but may occur, especially in xeroderma pigmentosum.

#### **CUTANEOUS LEIOMYOMAS**

These occur as solitary or multiple small nodules in the skin. They may be tender and painful, but this may not be apparent for years after the tumor has been first noted. The tumors consist of bundles of smooth muscle derived from the arrectores pilorum muscles or from vascular walls. They are usually benign and are probably best treated by surgical excision; electrocoagulation and

freezing with carbon dioxide snow have been used for eradication of multiple tumors.

#### **TUMORS OF THE SOFT TISSUES**

Neoplasms arising from muscle, fat and connective tissue comprise a miscellaneous but important group of tumors of early life. They may arise at almost any site and vary from benign neoplasms such as the lipoma to highly malignant sarcomas; the latter may be so undifferentiated as to preclude accurate determination of their cell of origin. They may occur at any age; among sixty-six congenital malignant neoplasms, exclusive of retinal tumors (Wells), there were thirty-three examples of sarcoma of various types. The most frequent manifestation is a visible and/or palpable mass; clinical differentiation of benign and malignant neoplasms is often impossible. Every solid mass should be considered malignant until proved otherwise by histologic examination of the excised mass.

Only some of the more common tumors of the soft tissues and some of those which present particular problems in diagnosis and treatment will be discussed.

**Lipomas** are benign, sharply circumscribed, rounded, lobulated tumors which may reach an enormous size. They are radiolucent and may be transilluminated; rarely calcific deposits may occur within the tumor. Rapid enlargement of these tumors may suggest a malignant change, but actual malignancy developing within a pre-existing lipoma is rare.

The most common site of these tumors, which may be multiple, is in the subcutaneous tissue. Small congenital lipomas may arise from the deep fascia on the palmar surfaces of the fingers and hands. A subcutaneous lipoma in the buttock may simulate a sacrococcygeal teratoma. Lipomas arising on the inner surface of the masseter muscle may extend into the parotid gland and simulate primary tumors of this gland.

**Retroperitoneal lipomas** are rare tumors usually arising in the perirenal region, which may attain a large size and distort or displace the renal pelvis or ureter. They may be circumscribed, easily removable lesions or diffuse tumors which cannot be completely removed. Sarcomatous areas may be present within these neoplasms.

**Mediastinal lipoma.** See page 1350.

**Diffuse lipomatosis** of an extremity may be present at birth, with resultant massive enlargement of the part; associated deformities of the adjoining bones may be present. In

her instances they are manifest as ill-defined tumors usually located in skeletal muscle. Complete removal may be difficult or impossible, and recurrences are common. Such diffuse lipomatoses probably represent a hamartomatous malformation rather than a true neoplasm and, in spite of recurrences, could not be misinterpreted as malignant neoplasms.

**Fibromas** are benign circumscribed neoplasms derived from fibroblasts. Pure fibromas are relatively rare, many of the tumors referred to as such being neurogenic in origin.

**Juvenile nasopharyngeal angiofibroma.** See page 1347.

**Dermatofibromas (sclerosing hemangioma, histiocytoma, subepidermal fibrosis)** are solitary, slightly elevated benign tumors of the skin. They are usually small, varying in size to 1 cm. in diameter, and on section are yellow and firm. The tumor consists of spindle-shaped cells often arranged about small spaces suggesting capillaries; vacuoles of eosinoid material, granules of hemosiderin and multinucleated giant cells are often present. They are interpreted by some as sclerosing hemangiomas.

**Desmoids** are fibromas of the musculoaponeurotic sheaths, most frequently in the anterior abdominal wall of women. Their neoplastic nature is not accepted by all observers, but their clinical behavior, with infiltration of surrounding tissues, continued growth and repeated recurrences, is certainly that of a neoplasm of low grade malignancy. The tumor may be present at birth or may first be noted in later infancy or childhood. They arise from aponeuroses usually in the abdominal wall and often involve the entire thickness of the wall. They are usually poorly circumscribed tumors which may recur even after apparently complete excision. Histologically, their appearance is that of a fibroma with inclusions of residual skeletal muscle within the tumor. Treatment should be by wide surgical excision.

**Congenital generalized fibromatosis** is an extremely rare condition characterized by the presence of multiple firm, spherical or ovoid fibroblastic tumors involving superficial and muscular tissues as well as viscera and sometimes bones. The lesions are present at the time of birth and are widely distributed over the body, but the more superficial ones show some predilection for the trunk, thighs and shoulder girdles. One of the masses may be dominant and suggest a primary neoplasm, but the multiple nodules appear to be in-

dependent growths (possibly hamartomas) and not metastatic lesions. Death occurs in the neonatal period.

**Fibromatosis of the plantar fascia** is of importance because it may be erroneously interpreted as fibrosarcoma and amputation performed; fibrosarcoma is even more uncommon than fibromatosis. Fibromatosis is manifest as single or multiple nodular swellings, sometimes associated with pain. They are usually not adherent to the overlying skin, and contractures are rare. Instances of congenital plantar fibromatosis have been reported. The lesion consists of interweaving bundles of cellular tissue composed of spindle-shaped cells. It is not clear whether this is an entity distinct from juvenile aponeurotic fibroma. Treatment consists in removal of the plantar fascia; incomplete removal may be followed by recurrence.

**Juvenile aponeurotic fibroma** is a rare lesion of childhood, appearing as a firm, painless, noncircumscribed tumor in the palm of the hand or sole of the foot. It is not associated with contractures of the part and is not fixed to the skin. Roentgenograms may reveal focal areas of calcification within the tumor. Although some of the tumors may be discrete neoplasms with ill-defined borders, others appear to arise multicentrically and to infiltrate fat and skeletal muscle; this lack of delineation may in part be responsible for the recurrences which may take place. The tumor consists of numerous plump, rather uniform nuclei oriented in one direction and embedded in a stroma of closely packed collagen. Areas of calcification may be present. The neoplasm is benign, although it may recur one or more times. Surgical excision (not amputation) is the treatment of choice.

**Neuromas** are not true neoplasms, but consist of proliferative masses of Schwann cells, axon fibers and connective tissue which develop at the proximal end of a severed nerve. They may be extremely painful.

**Neurilemmomas (schwannoma, neurinoma)** are benign, solitary, encapsulated tumors which arise from the peripheral, sympathetic or cranial nerves. The acoustic nerve is the commonest site of neurilemmoma arising from a cranial nerve. Peripherally located tumors are not likely to become as large as those in the posterior mediastinum or retroperitoneum. The tumor may be solid or partially cystic. Histologically it is characterized by palisading of the nuclei.

**Neurofibromas** may occur as solitary tumors or may be associated with multiple

neurofibromatosis (p. 1079). It commonly grows at the end of a cutaneous nerve, producing small, nonencapsulated tumors which may be single or multiple. Histologically it consists of interweaving bundles of fibroblastic-like cells with varying amounts of collagen. *Plexiform neurofibromas* may occur as isolated lesions or in association with *elephantiasis neuromatosa*, in which severe thickening of the part may be associated with hypertrophy of the bone. *Intraspinal neurofibromas* may occur singly or in association with multiple neurofibromatosis. The tumors may be entirely intraspinal or may penetrate an intervertebral foramen and produce a paravertebral mass.

**Neurofibroma of bone.** See page 1366.

**Giant cell tumors of tendon sheath origin** are small firm tumors arising from a tendon sheath or less frequently from an articular capsule. They are most frequent on the flexor surface of the fingers, less often on the toes. They resemble a fibroma containing foam cells and multinucleated giant cells. The tumor is benign, but may recur if incompletely removed.

**Benign mixed mesodermal tumors** are rare tumors which are usually small, nonencapsulated, and located in the soft tissues. They may contain a variety of mesodermal elements, including adipose tissue, smooth muscle and angiomatous areas. Some of these may be hamartomas rather than true neoplasms. Treatment is by surgical excision.

**Myxomas** are rare neoplasms which may arise in different structures, the more frequent ones being the heart, soft tissues and genitourinary system. Tumors in the soft parts may be soft and semitranslucent if superficially located; these features may not be apparent in more deeply situated tumors. They should be treated by wide surgical excision; otherwise recurrences are frequent.

**Sarcoma of soft tissues.** A variety of malignant neoplasms of mesenchymal origin occur in the soft tissues of infants and children and may be present at birth. The presenting complaint is usually that of a palpable mass, at times only recently noted and in other instances of relatively long duration. Differentiation of benign and malignant neoplasms of the soft tissues is usually impossible clinically, and the nature of the neoplasm is established only by histologic examination. In general, treatment is by wide local excision with removal of a substantial margin of surrounding normal tissue; the edges of the resected specimen should be examined histologically in

order to determine adequacy of the removal. Inadequate removal of sarcomas of even low grade malignancy may be followed by repeated recurrences or even by metastases. Sarcomas are usually radioresistant, but occasionally they may show some response to irradiation. Metastases are usually hematogenous rather than lymphogenous.

**Fibrosarcomas** vary from well differentiated tumors which are readily cured by local excision to highly undifferentiated neoplasms which are fatal in spite of wide excision. The better differentiated fibrosarcomas merge imperceptibly with the benign fibromas, whereas the fibroblastic origin of some of the highly undifferentiated neoplasms may be impossible to establish.

**Neurofibrosarcomas** (*neurogenic sarcoma*) may occur in patients with multiple neurofibromatosis or as solitary neoplasms; differentiation of the latter from fibrosarcoma may be impossible.

**Liposarcomas** are malignant tumors derived from fat and may occur at an early age. Only small amounts of fat may be demonstrable in some of these neoplasms. Although best treated by surgical excision, some of the tumors may respond to irradiation.

**Rhabdomyosarcomas** are malignant mesenchymal neoplasms revealing varying degrees of differentiation toward skeletal muscle. The more differentiated (but still highly malignant) neoplasms usually arise in the skeletal muscle of an extremity and are manifest by the presence of a mass deep in the affected part; they are rare in infants and children. Less differentiated neoplasms (embryonal rhabdomyosarcomas) tend to arise in the urogenital system and in the region of the head and neck, especially in the orbit, nasopharynx, soft palate, middle ear and maxillary sinuses; less frequently they may arise in an extremity. These are predominantly neoplasms of infants and children and may even be noted at birth. Embryonal rhabdomyosarcomas arising just beneath the mucous membrane of a hollow viscus or a body cavity may assume a grapelike or polypoid configuration and are referred to as sarcoma botryoides. The presenting complaint is usually that of a mass in the affected site, often with ulceration and secondary infection. The neoplasms are infiltrative and rapidly growing and may metastasize widely. The treatment of choice is wide surgical excision followed by irradiation. The prognosis is grave, but cures have been effected.

**Alveolar soft part sarcomas** occur pre-

ominantly in the muscles of the extremities of females. They are usually slowly growing tumors which may recur locally and may metastasize years after removal of the primary neoplasm. Their origin is not established, although some authors have suggested a relationship to nonchromaffin paragangliomas. Histologically they are characterized by a pseudoalveolar arrangement of the neoplastic cells in relation to delicate endothelial-lined vascular channels and septa. They should be treated by wide surgical excision.

**Leiomyosarcomas**, malignant neoplasms derived from smooth muscle, are rare in infants and children. They may arise in soft tissues as well as in the prostate and bladder.

**Synovioma** is a malignant neoplasm usually arising in the soft tissues near the knee; only rarely is the synovium of the joint involved. The neoplasm presents as a slowly enlarging mass involving the soft tissues. Recurrence is common, and the tumor metastasizes to regional lymph nodes, the viscera and bones. The prognosis is grave. Radical surgery is the treatment of choice, and some advise immediate amputation even for small circumscribed tumors.

## NEOPLASMS OF BONE

A variety of benign and malignant neoplasms of bone have been described in children in addition to non-neoplastic lesions which clinically and roentgenographically simulate true neoplasms. Roentgenographic studies are valuable for the detection and interpretation of osseous lesions, but diagnosis and treatment of suspected neoplasms of bone require clinical and *histologic* studies in addition.

### BENIGN NEOPLASMS AND NEOPLASTIC-LIKE LESIONS

**Osteochondromas** (*osteocartilaginous exostoses*) may be solitary or multiple. They probably represent anomalies of development rather than true neoplasms. Multiple exostoses are discussed on page 1244. The solitary osteochondroma is one of the most common of the benign osseous tumors. It is most frequently located at or near the ends of the long bones, especially the lower end of the femur or upper end of the tibia, but may arise from any bone which is preformed in cartilage. It usually manifests itself in childhood or adolescence by a bony protuberance; occasionally pain may result from a fracture through its stalk or from the development of an overlying bursitis. The tumor consists of

a bony mass near the epiphysis which protrudes in the direction of the shaft and is covered by a cap of cartilage. Growth of the mass tends to cease at or before cessation of skeletal growth. After cessation of growth the cap of cartilage may disappear, leaving only the residual outgrowth of bone (osteoma). Malignant transformation of an osteochondroma usually does not occur until after cessation of skeletal growth and is more frequently observed in the presence of multiple exostoses; the resultant neoplasm is usually a chondrosarcoma. It has been estimated that 5 per cent of patients with multiple exostoses will ultimately have malignant neoplasms from one or more sites. Surgical resection of the tumor should be performed whenever feasible as a prophylactic measure against malignancy.

**Enchondromas** are solitary benign cartilaginous tumors arising within the bones. They probably are hamartomas rather than true neoplasms. Skeletal enchondromatosis refers to the presence of such tumors in multiple sites; when the involvement is predominantly unilateral, the condition is referred to as Ollier's disease (p. 1245); when there are associated vascular malformations, it is referred to as Maffucci's syndrome.

Solitary enchondromas are usually located in cylindrical bones, especially in one of the short bones of the hands or feet. The initial symptoms are often pain and swelling following a pathologic fracture. Roentgenograms reveal a well circumscribed area of rarefaction within the bone, with or without expansion of it and attenuation of the overlying cortex; dense stippled foci representing areas of calcification are commonly present. There is usually no periosteal formation of new bone unless infraction of the cortex has occurred. Histologically, the tumors consist of lobules of atypical hyaline cartilage, the matrix of which may have undergone a myxomatous change. Malignant changes within an enchondroma may occur, but are not common. The development of chondrosarcoma in the short bones of the hands or feet is rare. Treatment of solitary enchondroma consists in curettage, and the introduction of bone chips or a bone graft if necessary.

**Benign chondroblastomas** are rare tumors derived from young cartilage cells. They occur predominantly in adolescent males and characteristically involve the epiphysal end of a long bone. The neoplasm manifests itself by pain which is often referred to the neighboring joint. Roentgenographically the lesion

appears as a rarefied mottled focus arising in the epiphysis, but sometimes extending into the adjoining metaphysis; it tends to be encircled by a narrow line of increased density. Histologically it consists of cellular areas of compact round or polyhedral cells, deposits of hyaline cartilaginous matrix, focal areas of calcification, necrosis and hemorrhage. The presence of multinuclear giant cells may lead to an erroneous diagnosis of giant cell tumor. Treatment consists in curettage with instillation of bone chips.

**Chondromyxoid fibroma** is closely related to benign chondroblastoma. It is a rare benign tumor usually encountered in the metaphysis of one of the long bones of the extremities. The lesion appears as an eccentrically located, expansile rarefied area in the metaphysis; the borders tend to be scalloped and well defined by a narrow band of opaque sclerotic bone. In small bones the roentgenographic appearance may be that of an expansile, pseudotrabeclated cyst occupying the entire width of the bone. Histologically the tumor consists of lobulated masses of closely packed cells embedded in a myxoid matrix; the latter may undergo extensive fibrosis, and in some areas recognizable cartilaginous matrix may be formed by the neoplastic cells. The tumor, although rare, is of importance because it may be confused with a malignant tumor, especially a chondrosarcoma. Curettage followed by instillation of bone chips usually suffices to cure the tumor, but recurrences may take place.

**Osteomas** are benign tumors composed of osseous tissue which arise in the bones of the face or skull and may project from the surface or extend into the orbit or paranasal sinuses. Other growths indistinguishable from true osseous neoplasms may represent the end stage of an osteochondroma or may be the result of reactive non-neoplastic formation of bone.

**Osteoid osteoma** is most frequently located in the tibia or femur, but may occur in other bones. The predominant symptom is pain, often with localized tenderness; swelling and, rarely, slight local heat and redness may be present. Roentgenograms may not demonstrate a distinctive lesion in the early stages. Characteristically, however, there is a small radiolucent area surrounded by a zone of sclerotic bone; the latter may extend well beyond the lesion and may obscure the area of radiolucency. In some instances the central nidus may be radiopaque and thus not be

visible within the dense peripheral sclerotic bone.

The tumor consists of a central nidus of sharply circumscribed osteoid tissue with varying degrees of mineralization. The dense peripheral zone noted on the roentgenogram consists of reactive, non-neoplastic bone. The tumor is benign and can be cured by complete removal of the nidus; failure to remove the nidus is followed by a recurrence of symptoms.

**Benign osteoblastoma** (osteogenic fibroma, ossifying fibroma, fibrous osteoma) is a rare neoplasm composed of a fibrous matrix with areas of osteoblastic activity, osteoid tissue and bone. It occurs predominantly in children and young adults and involves especially long bones, vertebrae and the maxilla and mandible. Roentgenographically, it is a well circumscribed lesion which may expand and attenuate the cortex; its inner border tends to be limited by a zone of sclerotic bone. Although the lesion is clinically benign, its histologic features may simulate those of an osteosarcoma as well as a variety of neoplastic and non-neoplastic lesions of bone. Complete clinical and roentgenographic data, as well as the histologic findings, must be carefully evaluated before accepting a diagnosis of benign osteoblastoma.

**Nonosteogenic fibroma** is a benign tumor which usually occurs near the end of the diaphysis of one of the long bones, especially in the lower extremity. The lesion may be asymptomatic, or pain, sometimes interpreted as arthritis, may occur. Roentgenograms reveal a rarefied, trabeculated lesion with a sharply outlined margin of sclerotic bone; the lesion is usually eccentrically located within the bone. The tumor consists of bundles of spindle-shaped connective tissue cells with no attempt at the formation of bone. Abundant hemosiderin pigment, multinuclear giant cells, foam cells and collagen may be present. The lesion can be successfully treated by curettage. Spontaneous healing may occur, however, and there is considerable doubt as to the neoplastic nature of the lesion.

**Neurofibromatosis** (see also p. 1079). Neurofibromas may involve the bones directly, with extensive destruction and deformity, or they may be associated with skeletal abnormalities such as scoliosis, pseudarthrosis, skeletal enlargement of part or of an entire extremity, or a defect in the wall of the orbit with unilateral pulsating exophthalmos.

**Giant cell tumors** are rare in childhood, since they characteristically occur in the ends of long bones after closure of the epiphyses. The majority of lesions interpreted as such are probably solitary unicameral cysts.

**Hemangiomas** may occur as primary osseous lesions or in association with hemangiomas in the adjoining soft tissues. Primary osseous hemangiomas are located especially in the vertebrae, although they may also occur in other sites. Roentgenographically, they may appear as pseudotrabeclated, cystic expansile lesions. In the skull a so-called sun-ray appearance may be noted on the roentgenogram. Hemangiomas of the vertebrae may involve two or more adjoining vertebral bodies and produce a vertical striated appearance; collapse of the vertebrae with pressure on the spinal nerve rootlets may be responsible for symptoms.

**Epidermoid Cyst.** See page 1361.

**Eosinophilic Granuloma.** See page 1004.

**Solitary unicameral cysts** are common lesions occurring in the metaphyses of long bones, especially in the upper ends of the tibia and humerus and lower end of the femur. They rarely occur after closure of the epiphysial line. The lesion is often symptomless until pain occurs after a pathologic fracture.

The lesions probably begin in the metaphysis, and growth of the bone displaces them away from the epiphysial plate. It causes a central rarefaction of bone, often with a pseudotrabeclular pattern (Fig. 424); the defect is usually no wider than the adjacent metaphysis, although expansion of the shaft may occur. The cortex is attenuated and may be fractured. The roentgenographic appearance may be similar to that of such conditions as fibrous dysplasia, enchondroma or eosinophilic granuloma. In contrast to the giant cell tumor and benign chondroblastoma, it does not cross the epiphysial plate.

The lesions are cystic and contain blood or fluid, which is often xanthochromic. The cyst is lined by a small amount of nonspecific vascular connective tissue containing deposits of hemosiderin, lipid-laden macrophages and multinucleated giant cells.

**Treatment** consists in curettage and packing with bone chips. Spontaneous healing may occur, especially after a pathologic fracture, but treatment is usually indicated.

**Aneurysmal bone cysts** may involve almost any bone; vertebral lesions probably constitute approximately one fourth of the cases. The presenting complaint is usually that of

pain, at times associated with a palpable mass; neurologic manifestations may be present with lesions of the vertebrae. Roentgenographically they appear as cystic expansile lesions which, especially in the long bones, tend to extend outward beyond the surface of the bone. Multiple incomplete septa are often visible within the radiolucent area. The expanded lesion is usually outlined by a thin shell of periosteal new bone, but rupture of this may occur with extension of the process into the adjoining soft tissues. Macroscopically, the cysts contain bloody fluid and soft, hemorrhagic or reddish-brown tissue; abundant blood may persistently obscure the operative field at the time of operation. Histologically they consist of pools of blood separated by septa of connective tissue; giant cells, hemorrhages and newly formed bone may be present within the septa. *Treatment* is indicated because of the tendency of the lesion

FIG. 424. Solitary unicameral cyst of lower end of femur. Note the "trabecular" pattern and expansion of the cortex. The epiphysis is intact, a characteristic of the lesion.

to progress and consists in curettage or less frequently in irradiation; even incomplete curettage may be followed by healing. The lesion probably is not a true neoplasm.

### MALIGNANT TUMORS OF BONE

By far the most frequent primary malignant tumors of bone are the osteosarcoma and Ewing's tumor, the majority of which occur between ten and twenty-five years of age, males being affected more frequently than females. Osteosarcoma characteristically involves the metaphysial end of a long bone, whereas Ewing's tumor involves the shaft, but roentgenographic differentiation of these two neoplasms is not always possible. Of greater importance, however, is the fact that many, if not all, of the roentgenographic features of these tumors may be duplicated by non-neoplastic lesions of bone. Accordingly, treatment of lesions suspected of being malignant tumors of bone should not be instituted until an unequivocal diagnosis is established by histologic study of the tumor. Moreover, the pathologist is limited in his ability to establish a diagnosis on the basis of histologic studies alone. For example, an actively growing callus about a fracture may closely simulate the histologic appearance of an osteosarcoma, yet correlation of the material obtained at biopsy with the roentgenographic findings may clearly indicate the true non-neoplastic nature of the process. Thus the pathologist must evaluate all pertinent clinical, roentgenographic and surgical data before he arrives at a diagnosis.

**Osteosarcoma** (osteogenic sarcoma) is more common than Ewing's tumor. It usually begins at the lower end of the femur or the upper end of the tibia or humerus, but may arise at other sites. The presenting complaint is commonly that of pain and swelling of the affected part, which the patient may attribute to trauma.

Roentgenographic studies reveal varying degrees of destruction of bone and of new bone formation. Codman's triangle is a radiopacity at the end of the tumor where the periosteum has been elevated. Neither this finding nor the perpendicular striations of new bone in the subperiosteal neoplasm ("sun-ray appearance") are always present, nor are they pathognomonic of an osteosarcoma. An elevated serum alkaline phosphatase, indicative of new bone formation, may be present.

The neoplasm at the time of amputation usually occupies the medullary cavity and has

FIG. 425. Roentgenograms of a Ewing's tumor of the tibia. A, The initial film revealed only slight periosteal proliferation. B, Roentgenogram, taken 3 months later, reveals cortical destruction and proliferation of new bone, the latter assuming a "sun-ray" appearance in some areas.

penetrated the cortex to the subperiosteal zone; penetration of the periosteum into adjoining soft tissues may also occur. The cortex, even though penetrated by neoplasm, may appear relatively intact or may be extensively destroyed. Histologically the appearance is varied, but consists essentially of atypical mesenchymal cells with varying degrees of formation of typical or atypical osteoid tissue and true bone. Cartilaginous areas and areas of myxomatous tissue may be present. Osteosarcoma commonly metastasizes to the lungs, although other organs may also be involved; osseous metastases are rare. Amputation appears to offer the best possibility of cure. The mortality rate, however, is high, but Dahlin has reported 19 per cent of patients surviving five years.

**Ewing's tumor** may involve the same bones as does osteosarcoma; in addition, there is relatively frequent involvement of the flat bones and the ribs. The initial complaints are often similar to those associated with an osteosarcoma; fever and leukocytosis may occur with either tumor, but are more likely to be associated with Ewing's tumor.

Roentgenographically, the lesion produces a mottled area of rarefaction, often associated with increased density and periosteal forma-

tion of new bone (Fig. 425). The latter may be deposited in layers, resulting in an "onion-skin" appearance, but this finding is often absent and may appear in association with other osseous lesions. The roentgenographic appearance may closely simulate that of osteomyelitis, osteosarcoma, eosinophilic granuloma of bone or metastatic neuroblastoma (Fig. 425).

Gross examination of an affected bone usually reveals more extensive neoplastic involvement than was demonstrable roentgenographically. Histologically the tumor consists of sheets of uniform round or oval nuclei with little or no cytoplasm. The neoplastic cells do not form new bone. Extensive areas of hemorrhage and necrosis are commonly present. The histologic appearance may be indistinguishable from that of a metastatic neuroblastoma, and every attempt should be made to exclude the presence of an extra-osseous primary lesion.

Ewing's tumor usually involves a single bone when first recognized, but ultimately many bones may be affected. Metastases to the lungs are also common. *Treatment* is unsatisfactory. Although the neoplasm usually responds initially to roentgen therapy, cures are rare. The results following irradiation are probably comparable to those obtained by amputation.

**Primary reticulum cell sarcoma of bone** often arises in a long bone and may simulate Ewing's tumor both roentgenographically and histologically; it is not accepted by all observers as distinct from Ewing's tumor. Metastases to lymph nodes occur more frequently than in Ewing's tumor, and osseous metastases are infrequent. Irradiation is probably the treatment of choice. The prognosis is more favorable than that of Ewing's tumor.

**Chondrosarcoma** is rare in children. It usually arises from the bones of the trunk or the upper ends of the humerus, femur or tibia. The clinical course is less rapid than that of osteosarcoma, and the prognosis, when amputation can be performed, is somewhat more favorable.

**Fibrosarcoma** may arise within the medullary cavity of a bone, commonly the lower end of the femur, or from the periosteum or adjoining connective tissue and erode the adjacent bone. It differs from osteosarcoma in that there is no tendency to formation of even atypical osteoid or bone. Roentgenographically the underlying bone may appear intact, or there may be areas of cortical destruction; the margins of the neoplasm are

usually poorly defined. *Treatment* consists in complete surgical resection or, if necessary, amputation; in general the prognosis is more favorable than is that of osteosarcoma.

**Multiple myelomas** are extremely rare in children. Roentgenographically they may simulate metastatic neuroblastoma, Ewing's tumor, acute leukemia, multiple eosinophilic granulomas, Hand-Schüller-Christian or Letterer-Siwe disease.

**Chordomas**, or tumors derived from remnants of the notochord, are rare in children. Although not strictly neoplasms of bone, they invade and destroy bone at their site of development, usually the sacrococcygeal region or base of the skull. They are locally invasive tumors which usually cannot be successfully removed; metastases are unusual. Some chordomas in children have been reported as responding to irradiation.

**Ameloblastomas (adamantinoma)**, which are epithelial tumors derived from remnants of the enamel organs, occur more frequently in the mandible than in the maxilla. Tumors arising in the maxilla may obliterate the antrum and bulge into the orbit, nasal cavity or mouth. Roentgenographically they are usually expansile, well circumscribed lesions, but they may penetrate into adjoining tissues. Recurrences following curettage are frequent, and rarely metastases may occur. Cranio-pharyngiomas (p. 1086) may have the histologic appearance of an ameloblastoma, and tumors of similar appearance have been reported in the tibia. Certain rare pigmented tumors occurring primarily in the maxilla of infants have been referred to as *melanoameloblastomas*; they may be derived from misplaced optic remnants (retinal anlage tumors).

**Odontoma.** See page 620.

# Radiation Injury

The roentgen ray, a form of ionizing radiation, is one of the components of atomic energy. Since in military, industrial and medical fields there is an increasing use of ionizing radiation, the possibility of untoward biologic effects is of special interest in relation to the child, for these effects may be most serious in growing tissues.

Ionizing radiation produces injury in the same manner regardless of the type of particle or ray emitted. The variation is quantitative rather than qualitative. The absorption of energy causes some of the molecules in the path of the radiations to become ionized. In attaining stability these molecules may form substances which alter, temporarily or perhaps permanently, biochemical processes within the cell or its environment. These effects upon cellular structures provide an explanation for the death of persons exposed to ionizing radiations, for the death of certain cancer cells treated with roentgen rays, for genetic mutations and for the production of cancer as a late effect of exposure to radiations.

Susceptibility of tissues to roentgen rays is, generally speaking, greater in the more rapidly mitosing and the more undifferentiated cells. Owing to an abundance of this type of tissue in the abdomen, a patient is more likely to have radiation sickness from roentgen therapy in this region than from comparable exposure of another part of the body.

**Dosage Factors.** Radiation absorption increases with the volume of the child's body exposed, with prolongation of exposure or with an increase in amperage or voltage. Absorption decreases in relation to the effectiveness of filters used and to an increase in distance between the patient and the roentgen tube.

Adverse acute effects of roentgen rays are diminished when the total dose is administered in several exposures separated by sufficient time for recovery from the subclinical effects of each. Repeated exposure to low doses of roentgen rays may produce pathologic

effects not manifest until years later. Some of the chemical changes produced in cells by roentgen rays are irreversible, and may lie dormant until aging, infection, hormonal alterations or further exposure to toxic agents makes them manifest.

The young infant may be more susceptible to the effects of roentgen rays than is the adult. However, even if there are no essential differences in susceptibility, his longer life span provides more time for such changes to develop.

Fluoroscopic dosages range from 1.5 to 40 roentgens per minute (mode—10 to 20). The dose required for a standard roentgenogram of the chest is 0.05 roentgen, whereas 15 roentgens is the average dose for a fluoroscopic examination of the same region, or 300 times that necessary to obtain the film.

Unfiltered machines in dental offices to secure roentgenograms of all the teeth (twenty-five to thirty exposures) may deliver as much as 315 roentgens to the head of the patient. Though not all these rays are de-

*Table 118. Customary Roentgen Ray Doses Used for Infants and Children, Measured in Air at the Point of Entry into the Patient's Body*

<i>Roentgen Procedure</i>	<i>Customary Roentgen Dose</i>
Fluoroscopy.....	10-20 r per minute
Chest film.....	0.05 r
Other common films.....	About 1.2 r each
Estimated dose to ovaries per examination of the abdomen.....	0.2 r
Intravenous pyelogram.....	7-8 r for a series of 6 plates
Barium enema studies, G-I series.....	10-20 r per minute for fluoroscopy and 1.2 r for each film
Dental film studies.....	1-15 r per film (average 5 r)
Diagnostic studies for congenital heart disease.....	140 r or more
Treatment of thymus.....	75-350 r
Treatment of acne.....	500-1000 r for a course of treatment

From R. W. Miller: *Pediatrics*, 11:294, 1953.

livered to the same portion of the patient's head, doses may be high in regions where the lines of radiation intersect.

Contrary to general opinion, roentgen rays in low doses do not have a stimulative action on cells.

**Early Effects of Irradiation.** Exposure of the entire body to 100 roentgens usually produces illness in man. A dose of 450 roentgens will cause death in 50 per cent of exposed persons. Higher doses can be tolerated if only a part of the body is exposed. Death results within hours to days when the entire body is exposed to the overwhelming dosage provided by an atomic bomb.

Symptoms of radiation sickness which vary with the exposure are malaise, fever, nausea, vomiting and diarrhea. Leukopenia develops rapidly, and in the more severe instances thrombocytopenia may appear within a week. When the initial symptoms are not severe, they are followed by a temporary period of well-being. Epilation begins about two weeks after the exposure. The leukopenia increases susceptibility to infection, and the low platelet count predisposes to hemorrhage. Death, if it occurs, might therefore be attributed to infection or hemorrhage. When an autopsy does not reveal the cause of death, it can only be assumed that the radiation injury was responsible for lethal "cytochemical changes." If the patient survives for six weeks, death is not likely from these effects of radiation.

Only a small percentage of deaths caused by an atomic explosion can be attributed to radiation effects alone; thermal and blast injuries account for most of them. Traumatic injuries do not heal effectively in persons with radiation sickness.

Therapy for radiation sickness resulting from exposure of the entire body is not very effective. Prophylactic administration of broad-spectrum antibiotics may diminish mortality. Transfusions of stored blood have not reduced the mortality in experimental animals or altered the bleeding diathesis. Transfusion of stored blood is therefore indicated only when the deficiency of red blood cells justifies it.

Dramamine and pyridoxine are partially effective in the relief of nausea, vomiting, headache and weakness from moderately severe radiation sickness.

**Late Effects of Irradiation.** Within the decade following the detonations of the atomic bombs in Japan there was a significant

rise in the incidence of leukemia in those who were within a radius of 1500 meters of the hypocenter (the spot on the ground immediately under the center of an air burst). The incidence of other hematologic abnormalities has not increased. Small lenticular opacities of the posterior capsule of the lens have developed in 85 per cent of those who epilated soon after the bomb explosion; the lesions are asymptomatic. Only ten of the thousands of survivors have grade III or IV radiation-induced cataracts. Microcephaly with mental retardation has occurred in infants exposed in utero to atomic radiation. The incidence of these defects was dependent on dosage and gestational age, susceptibility being greatest among those whose mothers had last menstruated seven to fifteen weeks before the detonation of the bomb. There is no doubt that genetic damage occurred, but it could not be demonstrated in the 80,000 first-generation offspring examined.

Radiation-induced premature aging, characterized by early senescence and death in middle age from diseases that ordinarily beset the elderly members of the species, has been described in animals, but has not been conclusively demonstrated in man.

That therapeutic doses of partial-body radiation may predispose to cancer is indicated by reports of a greater incidence of leukemia among adults treated for ankylosing spondylitis and of thyroid tumors among persons treated in early infancy for thymic enlargement. That repeated small doses of radiation to the entire body may predispose to leukemia is indicated by the increased incidence of this disease among radiologists.

Effects from exposure of part of the body include temporary sterility, dermatitis, bone and skin tumors and developmental defects in the teeth. There are several reports of arrest in bone growth in children who received cancericidal doses of roentgen rays.

**Radioisotopes.** Radioisotopes are providing new approaches to diagnosis, therapy and investigative studies. Hazards are comparable to those of roentgen rays, but the total amount of radiation is much less because of the small doses used. Biologic effects persist until the radioisotopes are excreted or until they disintegrate.

**Preventive Measures.** It is presently estimated that the allowable occupational radiation exposure (whole-body) for man is 0.1 roentgen per week. This dose is based on exposure of the gonads, because all doses re-

ceived by them are additive and presumably detrimental. The National Academy of Sciences has recommended for the *population at large* that the average cumulative gonadal exposure not exceed 10 roentgens per individual from conception to the age of thirty years; for the *individual* the cumulative dose should not exceed 50 roentgens.

The potentials for delayed somatic illnesses produced by partial-body radiation are not known, but it is thought that radiation changes within somatic cells are *incompletely* additive throughout life.

The child of today is likely to have repeated exposures to ionizing radiations, and there is a possibility that his tolerance may be dissipated. The pediatrician should limit as much as possible the exposure of his patients (and himself) to the emanations of roentgen ray machines and radioisotopes, but need not refrain from using them for essential diagnostic and therapeutic procedures. When a roentgen examination is needed, a film study should be obtained initially whenever possible, the exposure being far less than that for fluoroscopy. Subsequently fluoroscopic examination can be made if it is still required.

The duration of fluoroscopy can be shortened if no conversation is conducted during the examination. The machine should be operated only while the physician can use his eyes most effectively, i.e., after he has adapted to the dark and while he is thinking only of the picture before him—*not while he is trying to interpret the findings*. The field under study must be kept as small as possible by reducing the shutter opening to a minimum. The machine should be operated with the most effective filter available, with the roentgen-ray tube at the greatest possible distance from the patient, and with the lowest amperage and kilovoltage permitting adequate examination.

A pregnant mother should *not* enter a fluoroscopy or therapy room in the first trimester for fear of fetal injury.

Roentgen therapy should never be used except when the indications are unmistakable or the risk justified, as, for example, in the treatment of malignant tumors. Extreme care must be exercised to avoid unnecessary dam-

age to osseous growth centers, tooth buds and the various organs of the body.

Roentgen ray machines should be checked at least once a year for leakage which might be a hazard to personnel. The physician should wear his lead apron and gloves whenever the machine is in operation and should not expose unshielded parts of his body to the radiation beam.

A particular hazard for children is shoe-fitting by fluoroscopy. The machines are often poorly shielded and permit excessive leakage. The duration of the examination is prolonged by the interest of the child, and it is yet to be demonstrated that shoes cannot be equally well fitted by palpation.

# Poisoning from Food, Metals, Chemicals and Drugs

## FOOD POISONING

So-called food poisoning may be produced by (1) contamination of food by chemical poisons, (2) contamination by bacteria, and (3) chemical or toxic substances natural to certain plants or animals.

Contamination of food may occur at the source from insecticides, such as lead arsenate, or from preservatives or fungicides, such as formaldehyde or copper sulfate. Lead arsenate may be on fruits and vegetables in sufficient quantity to produce symptoms of acute or chronic poisoning. Foods may become contaminated after packaging. The container or its lining may dissolve in the food or enter into a chemical reaction with it. At times foods have been placed in containers previously used for mixing arsenic sprays or lead paints. Insect powders have been added to foods by mistake for baking powder or flour. Silverware cleaned with cyanide polish has produced poisoning. Ingestion of the flesh of cattle and fowl that have fed on fruits and vegetables heavily contaminated with arsenic may also cause poisoning.

Bacterial contamination of foods usually takes place from the time of preparation to the time of consumption. Poisoning may be caused by the toxins elaborated, as in staphylococcal poisoning, or by actual bacterial invasion of the intestines, as in *Salmonella* infections. A large variety of organisms may produce poisoning. The bacteria may contain an endotoxin or produce an exotoxin.

### BOTULISM

Botulism is an often fatal intoxication due to the ingestion of food containing the *Clostridium botulinum*, an anaerobic spore-former. The source of the infection is chiefly home-canned foods, especially vegetables. Several powerful exotoxins are formed. Types

A, B and E being most often present. They are not heat stable and can be completely destroyed by thorough cooking (80° C. for ten minutes).

**Symptoms.** Symptoms develop in twelve to forty-eight hours and are due to the curare-like action of the poison on the motor nerves and on voluntary muscles. There may be anorexia, weakness, dizziness, diplopia, ptosis of the eyelids, strabismus, and difficulty in breathing, swallowing and talking. Death may occur in one to eight days.

**Treatment.** In addition to lavage and catharsis, specific antitoxin with large amounts of glucose should be given intravenously as early as possible. Parenteral fluid therapy should be continued during the acute phase.

### STAPHYLOCOCCAL POISONING

Some strains of staphylococci produce an exotoxin in pastry and other starchy foods, and other strains may develop a soluble exotoxin in other foods. Such foods as salads, chicken, ham and beef in hash or in gelatin, whipped cream and custards, especially when prepared in large quantities some time before consumption, are likely to become infected unless caution is taken in their preparation and refrigeration.

**Symptoms.** The symptoms of staphylococcal poisoning appear suddenly within one to six hours after the ingestion of contaminated food and consist in severe nausea and vomiting with retching, abdominal pain, acute prostration and diarrhea. There may be blood and mucus in the stools. The temperature may or may not be elevated. There is frequently sweating, hypotension and shock. The course of the poisoning is usually limited to twelve to twenty-four hours. Staphylococcal poisoning should always be suspected

when an entire family or a large group of people become ill about the same time.

**Treatment.** If the patient is seen within the first few hours, a saline cathartic may be given. Food should be withheld until the diarrhea is controlled. The important measures, however, are supportive ones. Fluids should be administered intravenously to combat dehydration and shock as well as any acidosis.

### STREPTOCOCCAL POISONING

Certain of the hemolytic streptococci of group A may produce an exotoxin and be a cause of food poisoning. Symptoms and treatment are similar to those of staphylococcal poisoning.

### SALMONELLA POISONING

(See also page 442.)

The Salmonella group of bacteria is pathogenic to man and animals and includes a number of organisms which are commonly associated with food poisoning in addition to those which characteristically produce typhoid-like fever. All these organisms are enterotoxic, but produce variable systemic reactions. Animals such as mice, birds and pigs may have the disease or may be carriers only. The excreta, flesh or products of such animals in food may be the source of infection. The contamination of foods, however, is most likely to occur from persons with active infection and from human carriers.

## LEAD POISONING

Lead poisoning is relatively common in infants and children. The residual effects of the toxic action of lead on the central nervous system are at times permanent and may even be progressive for years.

Infants and children may ingest lead in paint, particularly from repainted cribs, furniture and window sills and from fruit covered with insecticides, lead nipple shields, face powders, lead soldiers and toys, colored crayons and chalks and water from lead pipes. Lead may also be inhaled from fumes, as from the burning of storage batteries.

The likelihood of permanent damage to the central nervous system increases with the duration of exposure to lead. Pica is a common habit in infants and children with lead intoxication, and the child who has been treated for lead poisoning often continues to ingest lead if the opportunity is available. The physician should recommend a different environment or be certain that all sources of lead are eliminated from the home.

The incidence of lead poisoning appears to be increasing in certain metropolitan areas in the eastern United States. Failure to repaint woodwork and walls permits flaking of old lead-containing paint to which small children have easy access. Surveys of the lead concentration in the blood of infants and children disclose that many infants have toxic blood levels with few or no symptoms.

Lead enters the body through the gastrointestinal tract, skin or lungs. Except in acute poisoning, it is a slow-acting poison, and

symptoms may develop insidiously and at times be intermittent. A single ingestion may produce no symptoms, but the same quantity distributed over a long time may be toxic. The slow absorption and gradual accumulation of lead within the blood and soft tissues produce the clinical features of progressive poisoning. In the gastrointestinal tract soluble lead salts are formed which are absorbed. Lead salts contained in dust may be absorbed from the respiratory tract and also from the intestines from swallowed saliva containing dust. A large part of the absorbed lead enters the portal circulation and is excreted by the liver. Lead that reaches the systemic circulation is deposited in bone and in soft tissues, particularly in the liver, kidney, pancreas and brain. In the brain there is intense edema, widespread vascular damage, destruction of brain cells, and neuroglia disintegration. In the peripheral nerves the axon may be destroyed. Lead is slowly transferred from soft tissues to bone, where it is deposited as insoluble tertiary lead phosphate along with calcium. Factors which facilitate deposition of calcium favor the deposition of lead; decalcification is associated with release of lead from bone.

The occurrence of symptoms depends upon the amount of lead in soft tissues and in the blood. The amount of lead in the urine roughly parallels the amount in the blood and is thus an indication of the rate of transport to or from the tissues.

The urinary concentration of lead in nor-

mal children may vary from 0 to 400 micrograms per liter. In lead poisoning it may range from 35 to 720 micrograms. The total urinary excretion of lead during a twenty-four hour period is more significant than the amount in a single specimen. Excretion of 80 micrograms per twenty-four hours usually occurs in children with symptoms of severe lead poisoning; 50 to 80 micrograms per twenty-four hours may indicate lead poisoning or unusual exposure to lead. The excretion of less than 50 micrograms per twenty-four hours can be considered normal. Circulatory failure, renal ischemia and damage in severe lead poisoning may inhibit excretion of lead.

The concentration of lead in whole blood of children without a history of lead poisoning or pica has been found to range from 0.003 to 0.054 mg. per 100 ml.

An increase in urinary coproporphyrin is a constant and early sign of lead poisoning.

#### ACUTE LEAD POISONING

**Symptoms.** Acute lead poisoning is rare and occurs after the accidental ingestion of lead salts (lead acetate, lead carbonate) or the inhalation of lead fumes. Nausea, vomiting and abdominal pain follow. There may be acute paresthesia, pain and muscular weakness and occasionally a hemolytic crisis with anemia and hemoglobinuria. Renal damage is common. Death from shock may result in two to three days. Symptoms of chronic lead poisoning may follow recovery from acute poisoning.

**Treatment.** Gastric lavage followed by catharsis with magnesium sulfate, general supportive measures and treatment for shock are indicated. Absorbed lead should be mobilized into the bone as outlined under Chronic Lead Poisoning. Recovery is slow.

#### CHRONIC LEAD POISONING

**Symptoms.** The symptoms of chronic lead poisoning depend upon the rate and degree of transport of lead from intestine or bone to the soft tissues or blood. Symptoms may develop progressively from those of a mild nature to the severe characteristic manifestations; or there may be, for months or even years, a sequence in which periods of mild symptoms alternate with symptom-free periods. In the infant or young child, owing to the extreme vulnerability of the central nervous system, a relatively short period of exposure may be followed by severe symptoms of encephalitis, even before anemia, colic,

peripheral neuritis or other milder symptoms have developed. Encephalitis may also be precipitated in an otherwise quiescent case by release of lead from bones during an intercurrent acute infection or metabolic disturbance. Mild symptoms are weakness, irritability, loss of weight, vomiting, anemia, pallor out of proportion to the anemia, headache, abdominal pain or colic, loss of appetite (particularly for breakfast) and insomnia. Severe symptoms are muscular incoordination, peripheral motor paralysis of the most commonly used muscles (dorsiflexors of the feet or wrists), joint pains, hypertension, bradycardia or labile pulse rate, encephalopathy with separation of sutures, convulsions, and edema of the optic nerve. Encephalopathy is common in young children, whereas severe abdominal colic is more frequent in adults.

**Diagnosis.** The principal diagnostic features are basophilic stippling in the red blood cells, a lead line in the gums, roentgenographic evidence of increased densities at the ends of long bones (Fig. 426) and along margins of flat bones, an excessive concentration of lead in the urine or blood and excretion of coproporphyrin in the urine. Roentgenographic evidence is lacking in the presence of rickets. The presence of lead in the gums or bones does not necessarily mean that the clinical symptoms are due to lead toxicity, and, conversely, lead intoxication may be present in the absence of evidence of lead in the bones. Spectrographic examination of the blood may also be of value.

When there is encephalopathy, the cerebrospinal fluid is under increased pressure and may contain a large amount of protein and a few cells, usually less than 100 lymphocytes. Transient albuminuria, hematuria and glycosuria may also be present. The glycosuria is renal in origin and results from tubular damage.

**Differential Diagnosis.** Acute lead poisoning may simulate acute gastrointestinal disturbances with acute abdominal pain. Both the acute and chronic forms may simulate poliomyelitis, postdiphtheritic paralysis, localized neuritis or polyneuritis and rheumatic fever. In infants especially, lead encephalitis must be differentiated from other forms of encephalitis, brain tumor, brain abscess and meningitis, particularly tuberculous meningitis. The lead lines in the bones may be similar to those produced by bismuth and other heavy metals. When there is glycosuria associated with encephalopathy, the possibility of diabetic acidosis must be eliminated.

**Prognosis.** The prognosis is generally poor. Approximately half of affected infants and small children have encephalitic manifestations, and among these the mortality rate is about 25 per cent. Of those who recover from the active encephalitic phase, at least one third have permanent neurologic and/or mental sequels. It has been stated that children who have mild or latent forms of lead poisoning usually recover completely without residual defects if the source of the poison is removed, but one may doubt that this is invariably so. One long-term study has shown that of twenty children who had only mild evidences of lead poisoning during infancy, nineteen were mentally retarded or manifested some specific defect in mental development three to nine years later. Vascular nephrosclerosis as a residual of lead poisoning has been described.

**Treatment.** The primary aim of therapy is reduction of the concentration of lead in the blood and tissues by (1) prevention of continued absorption of lead from the intestines or other sources; (2) an increase in the excretion of lead primarily through the urine. A secondary consideration, particularly important in the presence of encephalopathy,

is the promotion of deposition of lead in the bones. Supportive treatment is of the utmost importance.

**Prevention of absorption.** All sources of lead must be removed from the environment. If oral fluids can be tolerated, relatively large amounts of milk should be given to form insoluble, poorly absorbed lead salts in the intestines.

**Increase in excretion.** Salts of ethylenediamine tetra-acetic acid (EDTA) form a non-ionized chelate with lead which is nontoxic and is excreted in the urine. Decrease in the concentration of lead in the blood occurs rapidly after its administration. EDTA is usually administered by intravenous infusion. A test dose of 0.2 gm. diluted with 200 ml. of 5 per cent glucose in distilled water is administered intravenously over a one-hour period. Observation for untoward reactions such as rash, vomiting, tetany, lethargy or shock should be continued for four hours after completion of the test dose. If none appears, then 1 gm. dissolved in 200 ml. of 5 per cent glucose in distilled water is given intravenously. The amount and rate of administration of this solution depend upon the total dose to be given. The maximum dose for children should not exceed 1 gm. per 15 kg. of body weight per day. This amount is usually administered daily by intravenous drip for five days. The presence of continued signs and symptoms of lead intoxication or a rise in the blood concentration of lead may necessitate a second course of therapy after an interval of at least two days. The administration of calcium EDTA orally may be effective, but its actions are delayed when given by this route. The use of EDTA by any route is contraindicated when lead is present in the intestines, since it facilitates absorption of lead, and encephalitic symptoms may be precipitated. A roentgenogram of the abdomen to detect the presence of lead in the intestines should precede therapy with EDTA.

BAL (p. 1381) will also cause an increase in the urinary excretion of lead. BAL apparently combines with lead in the red blood cells, but not effectively in tissues and so is of little value in lead poisoning.

**Increasing deposition of lead in the bones.** Lead appears to be absorbed, transported, deposited and excreted similarly to calcium. A relatively high intake of calcium, phosphorus and vitamin D diminishes the solubility of lead in the blood and hastens its deposition in bone.

Disturbances of electrolyte equilibrium,

FIG. 426. Lead poisoning. Long bones of a child 20 months of age, showing an increase in the thickness and density of the zones of provisional calcification. The child chewed paint from her crib and presented with anemia and irritability.

often associated with acidosis, are common in lead poisoning. Correction of the disturbance is imperative, since the deposition of lead in the bones is inhibited in the presence of acidosis (see Parenteral Fluid Therapy, p. 191). Sodium citrate may be of value, not only in control of the acidosis, but also by its ability to form a soluble complex with lead which is excreted in the urine; the administration of 1 to 2 gm. three times a day has been associated with a decrease in the blood level of lead.

Infection also interferes with deposition of lead in the bones and consequently must be controlled.

**Treatment of lead colic.** Lead colic may be controlled by the use of antispasmodics, such as atropine, but on occasion opiates may be necessary. Lead colic is also often benefited by administration of calcium salts; 10 ml. of a 10 per cent solution of calcium gluconate or 10 ml. of a 5 per cent solution of calcium chloride may be given slowly by the intravenous route.

**Treatment of encephalopathy.** In addition to the therapeutic measures outlined above, the increased intracranial pressure and associated complications of encephalopathy require additional considerations. The most careful observation and the provision of constant nursing care are required.

Convulsions are best controlled by phenobarbital administered intramuscularly (p. 1122). Care must be taken to avoid further depression of the damaged brain by excessive sedation.

The increased intracranial pressure may necessitate repeated, carefully performed lumbar punctures using a small-bore needle. Only small amounts of fluid should be removed at one time, owing to the extreme

danger of brain-stem herniation; carefully performed, the procedure may be lifesaving. Surgical decompression by craniectomy may occasionally be necessary.

Oxygen should be administered for even mild evidences of respiratory depression.

Correction of fluid and electrolyte disturbances is imperative, but must be carried out with caution. Excessive administration of water and electrolytes may increase the cerebral edema, as may dextrose in an electrolyte-free solution. Dextrose in a hypotonic saline solution is the solution of choice; quantities of water and electrolytes are best gauged by the combination of clinical (hydration, adequate urinary output, blood pressure and evidences of increased intracranial pressure) and laboratory (carbon dioxide and/or pH, sodium, chloride and potassium) evaluation. Underhydration is safer than overhydration.

Urinary retention is common and may require intermittent or continuous catheterization.

Central nervous system stimulants are rarely indicated. The severity of the involvement of the brain makes their use ineffective, and they may cause further damage.

**Retreatment.** The initial course of therapy may eradicate the clinical manifestations of lead poisoning, even while lead remains in the bones. The residual lead is often liberated gradually and excreted without renewal of symptoms of toxicity, but the reverse may be the case, especially with intercurrent infection. The necessity for retreatment will depend upon a significant rise in the concentration of lead in the blood and the return of manifestations of toxicity. Close observation for long periods of time is essential for prevention of additional damage to the central nervous system.

## CHEMICAL AND DRUG POISONING

### GENERAL CONSIDERATIONS

In the United States accidents and poisonings account for the largest number of deaths in the pediatric age group, more than the next seven causes of fatalities combined.

Over 1400 fatal poisonings occur each year in persons of all ages; one third of these occur in children under the age of fifteen, and approximately four fifths are in children of one to four years. Nonfatal poisonings are estimated to be 100 to 150 times the number

of reported fatalities. Poisoning is more frequent in boys than in girls under the age of five years. The frequency and causes of poisoning vary in different sections of the country and between rural and metropolitan populations. Death from petroleum products is more frequent in the southern states and is six times more frequent in the nonwhite population than in white children; lye poisoning is four times more frequent in the southern states and three times more frequent in rural than in urban communities. Chronic

lead poisoning, which affects children primarily between the ages of one and four years, has been more prevalent in recent years in some metropolitan areas in the eastern half of the United States.

### PREVENTION OF POISONING

The majority of cases of accidental poisoning in childhood are preventable. The responsibility for prevention lies not only with the parents, but also with the child's physician.

In the home, parents have a primary responsibility to keep medicines and poisons out of the reach of the naturally curious child. Highly poisonous substances should be locked in cabinets, and all medicines and poisonous chemicals should be properly discarded when they are no longer needed. Poisons should never be stored with foods. All medicines and chemicals should be kept in their original containers, which should be properly labeled. The physician and the pharmacist by meticulous attention to accurate prescription writing and compounding may prevent many cases of poisoning. Prescriptions containing poisonous drugs should be written for small quantities sufficient only for the immediate medical need. Proprietary medicines should be properly labeled with instructions and precautions regarding administration to children. Particular attention to the dangers of candy medication is imperative, since it is responsible for as much as 87 per cent of the cases of aspirin poisoning.

Parents fail to realize that a number of common household substances are poisonous; legislation requiring manufacturers to declare the presence and the nature of the hazardous ingredients on the labels of household products is essential. Caution must be taken in the storage of many household products such as bleaches, polishes and insecticides which, as a group, account for nearly one third of accidental poisonings. These substances are often stored in cabinets under sinks and are easily accessible to the young infant.

Safety instructions to parents should become a routine part of pediatric care when the infant is about six months of age.

### DIAGNOSIS OF POISONING

Acute poisoning may simulate many acute diseases such as peritonitis, intestinal obstruction, appendicitis, acute diarrheal disease, tetany, meningitis or encephalitis. When adequate evidence cannot be found for the symptoms of an acutely ill child, poisoning should

be suspected, and gastric lavage should be considered. Symptoms occurring in several persons after ingestion of food from the same source are strongly suggestive of food poisoning.

*The action of many poisons may be characteristic.* Gastrointestinal disorders with vomiting, diarrhea and abdominal pain occur commonly in metallic, acid, alkali, veratrum and bacterial poisonings. Convulsions are characteristic of poisoning by central nervous system stimulants such as camphor, picrotoxin and strychnine and by poisons producing anoxia from methemoglobin formation. Central nervous system depressants, such as alcohol, atropine (initial effect is stimulation), chloral hydrate, barbiturates, opiates, chloroform and others causing anoxia may produce coma. Dilated pupils suggest poisoning from atropine, nicotine (late), cocaine and ephedrine. Pinpoint pupils may be due to opiates, physostigmine, muscarine and nicotine (initial). Caustic alkalis produce lesions of the mucous membranes of the mouth and skin. The odor of some poisons is characteristic—for example, turpentine and eucalyptol, which may impart an odor of violets to the urine.

Mercury poisoning tends to cause marked albuminuria; poisoning by other metals, boric acid and phenol derivatives, a moderate albuminuria. Intense cyanosis and dyspnea suggest poisoning by carbon monoxide, cyanide, strychnine, aniline derivatives or botulism. Cherry-red mucous membranes are associated with carbon monoxide poisoning.

**Methemoglobinemia.** This is caused by many poisons and deserves special attention, since the resulting anoxia may lead to death or serious disturbance of vital functions: Nitrites, aniline derivatives, acetanilid, pyridium, dinitrophenol and potassium chlorate are the poisons which most commonly produce methemoglobinemia. Relatively small amounts of methemoglobin (15 per cent of the total hemoglobin) may produce recognizable cyanosis, which is usually more gray than blue and often not associated with dyspnea. When methemoglobinemia is suspected, a drop of blood should be placed on a slide beside a drop of normal blood; normal reduced hemoglobin becomes a bright red, whereas methemoglobin or sulfhemoglobin shows no change. Spectroscopy reveals a dark band at 618 millimicrons which does not change on addition of potassium cyanide to the blood.

The symptoms of methemoglobinemia are

those of anoxia and are related to the concentration of methemoglobin in the blood. A concentration of 15 per cent produces only cyanosis, particularly acrocyanosis; up to 20 per cent it causes mild fatigue and cyanosis, and 30 to 40 per cent may produce weakness, fatigue, tachycardia, nausea and generalized pains. Over 40 per cent concentration causes weakness, fatigue, tachycardia, confusion and coma, and death may occur.

**Identification of the Poisonous Agent.** Attempts should be made to identify the poison in every instance. If it is known that the child has ingested some household substance or drug, knowledge of its use may be of value in diagnosis. If the specific contents are not listed on the label, the container or bottle should be obtained and information concerning its contents sought from the prescribing druggist, poison control center or manufacturer. If this information is not available, the residual gastric contents should be analyzed. Emergency treatment should not be delayed until an analysis can be done, but identification of the poison may determine later aspects of treatment and ultimate prognosis. The first emesis or initial lavage specimen and a specimen of urine should be saved for analysis. Analysis and the clinical picture may be complicated by the fact that many household products and prescriptions contain several potentially poisonous ingredients. Approximately 50 per cent of poisonings are due to such medications as salicylates, especially aspirin, laxatives, sedatives and cough preparations; cleaning, polishing and sanitizing agents such as bleaches, lyes, furniture polishes and cleaning fluids are responsible for at least 25 per cent, and petroleum products, including kerosene, produce 10 to 20 per cent.

#### GENERAL TREATMENT OF POISONING

The treatment of acute poisoning is always an emergency. Time cannot be taken initially to analyze the poison ingested, and most emergency treatment is, of necessity, symptomatic. Procedures to be followed are (1) removal of the poison, (2) administration of an antidote, and (3) general or specific supportive and symptomatic treatment. At times it is necessary to give a specific antidote before removal of the poison is attempted.

**Removal of the Poison.** Poisons on the external surface of the body and in the nasal and oral cavities should be removed by copious irrigation with water. Acids should be

neutralized with weak bases, and alkalis with weak acids. If toxic oils are present, organic solvents should be applied, and removed with a mild soap solution. Orally ingested poisons may be removed by inducing emesis or gastric lavage. Immediate induction of vomiting may be lifesaving and can be carried out by the parents before the doctor's arrival. Emesis may be induced by administering a strong salt solution or powdered mustard in lukewarm water followed by stimulation of the posterior pharynx with the finger. The child should be held with his head dependent to avoid aspiration. Drug emetics are usually ineffective and may intensify the depressing action of some poisons. Emesis should never be induced in a comatose patient or after ingestion of caustic alkali or kerosene. Lavage is also not without danger. In corrosive poisoning the esophagus may be perforated; in strychnine ingestion the stimulation of a lavage tube may induce a fatal convulsion, and in kerosene poisoning, lavage, improperly done, may cause aspiration and pneumonia.

Gastric aspiration should be performed with caution. The child should be properly restrained, with his head slightly dependent and his face turned to one side. The gastric contents should be removed with a well lubricated, large-bore (28 French or larger) catheter, using an Ewald aspirating bulb. Small amounts of lavage solution (150 to 200 ml.) should be injected and aspirated as many times as necessary to remove all traces of the poison. Two to 4 liters of solution should be used. Water, weak salt and sodium bicarbonate solutions may be used until a more suitable solution is available. Activated charcoal mixed with water will absorb large amounts of alkaloids such as strychnine, morphine and atropine as well as mercuric and arsenic compounds. Tannic acid also precipitates alkaloid and metallic poisons, and strong tea may be used. Magnesium oxide suspensions are of value in mineral acid poisoning. Potassium permanganate 1:5000 solution will oxidize various organic poisons.

**Administration of an Antidote.** Antidotes for poisons are of two types—chemical and physiologic. A chemical antidote renders the poison innocuous or unabsorbable by direct chemical combination, absorption, adsorption or covering of the poisonous particles with a protective coating. Physiologic antidotes combat the effects of poisons after absorption. Unfortunately, specific chemical and physiologic antidotes are not available for all poisons.

The *universal antidote* for unknown poisons consists of 2 parts of pulverized charcoal, 1 part magnesium oxide, 1 part tannic acid; the dose is 4 ml. in a small glass of warm water. Milk and egg white are more or less specific chemical antidotes for metallic poisons. Strong tea, tannic acid and dilute iodine solutions are effective against alkaloids. Sodium formaldehyde sulfoxalate, if given immediately, is effective in the treatment of mercury poisoning. Nitrites and sodium thiosulfate have a specific action in cyanide poisoning. Methylene blue is indicated in methemoglobinemia, and ascorbic acid given intravenously may also be effective. Methylene blue is of questionable value in sulfhemoglobinemia and in large doses may produce further methemoglobin. Epinephrine, strychnine, picrotoxin and inhalations of oxygen and carbon dioxide may be indicated when anoxia and central nervous system depression are present. Stimulant and convulsive poisons demand sedation.

Gastric lavage may be followed by a large dose of a saline cathartic to hasten removal of poisons from the gastrointestinal tract. Catharsis is contraindicated, however, in severe phosphorus poisoning when bloody diarrhea and desquamation of the intestinal mucosa are present. Magnesium sulfate may produce severe central nervous system depression because the rate of absorption of magnesium from the bowel may exceed the rate of excretion, particularly if there is oliguria or renal damage.

*British anti-lewisite* (BAL, 2,3-dimercaptopropanol) deserves special mention, owing to its remarkable effect on some metallic poisons. The action of the metallic ions, particularly mercury and arsenic, is thought to be due to their chemical combination with important tissue sulfhydryl groups. As a result, essential enzyme systems requiring free SH groups are inactivated. The administration of BAL can reverse the inhibiting action of antimony, bismuth, chromium, nickel, copper and zinc on the sulhydryl enzymes. BAL is ineffective in poisoning caused by tellurium, thallium or vanadium. Under certain conditions it may augment the toxic effects of lead and may actually hasten death in poisoning due to cadmium and selenium.

Undesirable side effects are common with administration of BAL. These are lacrimation, salivation, nausea, vomiting, headache, pain in teeth, a burning sensation of the lips, mouth, throat and eyes, sweating, generalized muscular aching with burning and

tingling of the extremities, a sense of constriction in the chest, tachycardia, fever and agitation. Toxic symptoms begin within ten to fifteen minutes after injection and gradually subside within one to two hours. (For dosage schedule of BAL see Treatment of Arsenic and Mercury Poisoning.)

Certain metallic poisonings, particularly lead, mercury and iron, have responded to treatment with ethylenediamine tetra-acetic acid (EDTA), a synthetic polyamino acid. Various soluble salts of this compound such as calcium disodium versenate have the property of forming virtually nonionized metal complexes (chelates) with divalent and trivalent metal ions. The chelate is less toxic than the ionized metal and is excreted in the urine. Increase in the excretion of lead and mercury results without increase in toxicity. Toxic reactions of these chelating compounds have not been clearly defined.

Experience is being accumulated to show that performance of an exchange transfusion may be of value in accidental poisoning. Exchange transfusions should be considered for poisoning with methyl salicylate, boric acid, paranitraniline, chlorinated hydrocarbons, benzene, chlorate and bromate, copper sulfate, cyanide, dicoumarin, ferrous sulfate, naphthalene, phenol and thiocyanates.

**Supportive Therapy.** Excessive manipulation of the child must be avoided at all times, and medications, particularly stimulants and sedatives, should be administered with caution. Overtreatment may cause more damage than the poison itself. General supportive therapy is frequently more effective than removal of the poison or administration of specific antidotes. The type of supportive therapy required is dependent upon the actions of the poison involved. All organ systems of the body may be affected by poisons, and toxicity of one system may seriously affect other vital functions; e.g., respiratory depression may be secondary to central nervous system intoxication.

The nervous system is exceptionally vulnerable to the toxic action of poisons, but the symptomatology is variable. Evidence of stimulation or depression is usually noted. Stimulation results in convulsions, restlessness, confusion, and delirium. Sedation is frequently indicated, but must be administered with caution to avoid depression. Sedation also masks many signs and symptoms, making evaluation of the patient's condition difficult. Depression of the central nervous system is the most dangerous complication of

poisoning. It is manifested by lethargy, stupor and coma. Central nervous system depression commonly affects the cardiovascular, renal and respiratory systems. Prompt, intensive therapy is mandatory and is directed toward stimulation of the central nervous system and support of other systems affected.

The respiratory system is affected by many poisons, and the patient must be observed for evidence of respiratory depression, obstruction, pulmonary edema and pneumonia. Tachypnea may result from central nervous system stimulation and produce respiratory alkalosis. Artificial respiration, administration of oxygen and maintenance of a patent airway may be imperative.

Involvement of the cardiovascular system is frequent. Peripheral circulatory collapse may occur and must be combated by intravenous administration of saline and glucose solution, plasma or blood and possibly sympathomimetic vasoconstricting agents. Cardiac failure may occur initially or later, and disturbances of the heart rate and rhythm require emergency treatment.

Some poisons cause intense gastrointestinal irritation with severe vomiting and diarrhea. Replacement of the water and electrolyte loss by parenteral fluid therapy is imperative. Nausea, pain and abdominal distention may be severe.

Poisons affect the kidney either by direct toxic action or by the production of shock with renal ischemia. The most important aspect of therapy is administration of the correct amounts of fluids and electrolytes which will maintain homeostasis of the intracellular and extracellular fluid compartments. The extent of renal damage varies from mild involvement to acute tubular necrosis. If metabolic equilibrium is maintained by the judicious use of fluids containing electrolytes, glucose and protein, severe renal damage may be reversible. Hypertension from renal or peripheral vascular involvement is frequent. Urinary retention may also result from bladder atony or vesical neck spasm, and repeated catheterizations or the insertion of an indwelling catheter may be necessary.

There is a wide variation in the extent of liver involvement in poisoning, from minimal damage to severe necrosis. Supportive therapy is primarily the provision of a diet high in protein and carbohydrate and low in fat content, with vitamin supplementation. The extent of recovery is variable, but considerable regeneration of poisoned liver cells does occur. A serious secondary manifestation of hepatic

toxicity is depletion of prothrombin, and vitamin K administration is indicated prophylactically.

Disturbance of fluid and electrolyte balance is associated with many poisonings. The types, amounts and methods of administration of fluids and electrolyte-containing solutions must be selected for the individual case. The following are general considerations:

1. Administration of total fluids in amounts adequate to meet the daily body requirements.
2. Avoidance of water intoxication, hyper-electrolytemia or hyponatremia resulting from administration of inadequate or excessive amounts of water and/or electrolyte-containing solutions.
3. Correction of any potassium and/or calcium imbalances.
4. Maintenance of an adequate caloric and vitamin intake. Oral feedings are preferable for children if they can be retained.

The control of body temperature is frequently impaired, and avoidance of extreme hyperthermia or hypothermia is important. In barbitol and opiate poisonings the depressant action of these drugs is intensified by hypothermia.

The child who is poisoned may be susceptible to infection, and use of antimicrobial agents should be considered, but not instituted routinely. Antibiotic therapy is indicated for the prevention of secondary bacterial infection in poisoning by kerosene and other hydrocarbons which produce chemical pneumonitis.

The child may often be in severe pain, which must be alleviated. In planning the management of the child who has been poisoned the provision of competent, continuous nursing care must never be overlooked.

## CHEMICAL POISONING

Treatment of poisoning consists in general supportive care when the toxic substance is unknown, and specific when the substance is identified and definitive therapy for it is established. In each instance efforts should be made to identify the toxic agent. The chemical constituents of many medicinal, household and chemical products are recorded on the labels, and this practice must become increasingly common. If the chemical composition is not recorded, it may be obtained from the manufacturer, textbooks of toxicology, poison control centers or municipal or state toxicologists.

It is impossible to include in a pediatric textbook all known toxic chemical substances.

In the following sections a number of potentially toxic chemical compounds are listed. This chapter includes general classes of chemicals (alphabetically arranged) with associated signs and symptoms of toxicity and recommended therapy. The List of Chemicals (p. 1394) includes individual chemical compounds. Many chemicals are now assigned commercial or trade names, and, in general, these are used rather than the chemical nomenclature. Synonyms are also listed.

1. **Abrin.** The toxic albumin found in jequirity beans. Ricin is a related toxic albumin found in castor beans. One bean thoroughly chewed may cause fatal poisoning. Toxic material causes hemolysis of red blood cells at extreme dilutions. In acute poisoning, vomiting, diarrhea and circulatory collapse may occur. Symptoms may be delayed one to three days. Hemolysis, hemorrhages and edema of the gastrointestinal tract occur.

**Treatment.** Gastric lavage followed by catharsis and treatment for shock are indicated.

2. **Acids, Corrosive, and Acid-Like Substances.** Corrosive acids produce irritation, blistering and destruction of mucous membranes within a few moments after ingestion. Lesions may be brown or black except with nitric and picric acids, which produce yellow stains. Severe burning pain in the mouth, pharynx and abdomen followed by bloody vomiting and diarrhea may occur. Shock followed quickly by death occurs in approximately half of the cases. Esophageal stricture occurs in the majority of patients who recover.

**Treatment.** Water, milk or beaten eggs should be given immediately and repeated to dilute any free acid. Gastric lavage is not without danger at any stage and probably should not be performed later than one-half hour after ingestion. Later, perforation of the esophagus may occur. For more detailed treatment see page 643.

3. **Alcohols and Glycols. Methyl alcohol.** Ingestion of 3 to 8 ounces may be fatal. The metabolic products, formic acids or formaldehyde, inhibit cellular metabolism. Toxic and degenerative changes in the liver, kidneys, heart and brain occur. Optic atrophy may follow recovery from acute poisoning. Ethyl alcohol may competitively block metabolism of methyl alcohol.

**Treatment.** Gastric lavage and immediate intravenous administration of large amounts of alkali to combat severe acidosis. Potassium should be administered to correct the hypokalemia.

**Ethyl alcohol.** Signs and symptoms are primarily those of central nervous system depression. Fatalities occur at blood alcohol concentrations above 0.3 to 0.5 per cent.

	Blood concentration
Mild intoxication . . . . .	0.05–0.15 %
Moderate intoxication . . . . .	0.15–0.3 %
Severe intoxication . . . . .	0.3 –0.5 %
Coma . . . . .	Above 0.5 %

Blood  
Fatal dose for an adult . . . . 300–400 ml.

**Treatment** is supportive.

**Ethylene glycol, diethylene glycol.** These substances are metabolized to oxalic acid (see oxalates and oxalic acid). Central nervous system depression, shock and anuria may occur within a few hours, and respiratory failure and pulmonary edema occur within twenty-four hours.

**Treatment.** Lavage, catharsis and calcium gluconate.

4. **Aluminum and Zinc Salts.** Aluminum and zinc salts are used as astringents, deodorants and antiseptics. Symptoms consist of burning pain in the mouth and throat, vomiting, watery or bloody diarrhea, anuria, hepatic damage, collapse and convulsions.

**Treatment.** Immediate dilution with water or milk followed by repeated gastric lavage (see No. 2 and No. 49).

5. **Amphetamine, Privine, Ephedrine and Related Drugs.** Acute poisoning from ingestion, inhalation, injection or application to mucous membranes produces nausea, vomiting, chills, cyanosis, nervousness, irritability and fever. Blurred vision, mydriasis, altered ocular reflexes, spasms, convulsions, coma and respiratory failure may follow.

**Treatment.** Lavage and catharsis are indicated. Administration of barbiturates may be followed by severe depression.

6. **Aniline, Dimethylaniline, Nitroaniline, Toluidine and Nitrobenzene, Acetophenetidin, Acetanilid.** These dyes are used in paints, paint removers, printing inks and cloth marking inks and as solvents. Aniline poisoning of infants may occur from dye materials recently stamped on diapers or shirts. Paranitraniline is found in some yellow and orange wax crayons. A roentgenogram of the abdomen may show the opaque pieces of crayon in the intestine. Intense methemoglobinemia is produced by all these compounds. Symptoms include cyanosis, headache, shallow respiration, dizziness, hypotension, convulsions and coma. Hemolytic anemia may occur later. Five to 20 gm. of acetanilid may be fatal; a single dose of 0.5 to 5.0 gm. produces sweating, chills, gastric irritation, tinnitus, hypotension and circulatory collapse.

**Treatment.** Removal of poison from skin, repeated gastric lavage followed by catharsis. Oxygen, transfusion, exchange transfusion and methylene blue are of value.

7. **Antimony.** After ingestion, nausea, vomiting and severe diarrhea occur. Anemia, eosinophilia, hemoglobinuria and hematuria may be present.

**Treatment.** See No. 9.

8. **ANTU.** Antu produces massive pulmonary edema and pleural effusion in experimental animals by its action on the pulmonary capillaries and by increasing lymph flow. It is thought to be relatively nonpoisonous to man; more than one pound of a 20 per cent mixture has been ingested without producing symptoms.

9. **Arsenic.** Arsenic poisoning may be acute, subacute or chronic. Arsenic compounds may be absorbed from the gastrointestinal tract, lungs and skin. Arsenic inactivates sulfhydryl-containing enzymes and inhibits cellular respiration. It is stored in the tissues for a long time and is excreted slowly in the urine and feces. The more soluble salts may produce death quickly. In *acute poisoning*, symptoms usually occur within one-half to one hour after ingestion. If arsenic is ingested with a meal, there

may be delay as long as twelve hours. Constriction of the throat with dysphagia, intense gastric pain, persistent and projectile vomiting of large amounts of "rice water" occur; a severe watery diarrhea, becoming bloody, is common. The loss of fluids leads to severe dehydration, oliguria, hematuria and albuminuria. Eventually shock develops with cardiovascular and respiratory failure, terminating in coma and convulsions.

**Subacute or chronic poisoning.** If the patient survives the acute phase, there may be residual symptoms such as multiple neuritis, myelitis and hypoplastic anemia. Alopecia, dermatitis, macular erythema and pigmentation of the skin may also occur. In chronic arsenic poisoning due to ingestion of small amounts of arsenic over a period of time the development of symptoms is insidious with weakness, languor, anorexia, occasional nausea and vomiting, and constipation or diarrhea. Later, coryza, nasal and conjunctival congestion, edema of the lower eyelids, stomatitis, salivation and a garlic-like odor to the breath are present. The early symptoms may be followed by or be associated with any of the residual signs of involvement of the nervous system, the liver or the hematopoietic and epithelial tissues that occur in patients surviving acute poisoning. Pigmentation, hyperkeratosis of the soles and palms and exfoliative dermatitis are sometimes striking.

**Treatment.** Even though symptoms of acute arsenic poisoning are present, intensive and repeated lavage is indicated. If the patient is seen early, repeated lavage with a freshly prepared mixture of ferric hydroxide and magnesium oxide is said to be of value. Intensive intravenous hydration therapy is necessary. Sedation and morphine for pain are advisable.

BAL should be given promptly. The recommended intramuscular dose is 2.5 to 5 mg. per kilogram every four hours; the larger amount is approximately half of the toxic dose, so that undesirable side effects are frequent (see p. 1381 for toxic reactions). For mild arsenic reactions each injection should provide 2.5 mg. of BAL per kilogram of body weight. Four injections are given on each of the first and the second days; two on the third day, and one injection on each of the following ten days, or until recovery. For severe arsenic reactions, each injection should provide 3 mg. per kilogram. On the first and second days six injections are given each day at intervals of four hours; on the third day four injections are given, and subsequently, until recovery, two injections are given daily. Dosage schedules are essentially the same for reactions to gold.

Treatment should also be directed toward support of the damaged nerve, liver and kidney tissues.

**10. Aspidium, Male Fern.** The oleoresin, used as a vermifuge, produces progressive vomiting, diarrhea, abdominal pain, headache, colored or blurred vision, tremors, collapse, convulsions and death in respiratory failure. If recovery occurs, jaundice and blindness may persist for weeks.

**Treatment.** Gastric lavage followed by catharsis and general supportive measures. Castor oil and other oily cathartics should be avoided.

**11. Asterol.** A commercial fungicidal agent used against tinea infections. It has been reported to pro-

duce generalized muscular contractions. The sensorium is clear. There may be rotatory nystagmus and mydriasis.

**Treatment** is supportive.

**12. Atropine.** Active alkaloid of a number of the Solanaceae, which include *Datura stramonium* (Jimson weed, thorn apple), *Hyoscyamus niger* (henbane), *Datura arborea* (angel's trumpet), *Solanum nigrum* (black or deadly nightshade), *Solanum pseudocapsicum* (Jerusalem cherry), *Solanum dulcamara* (true bittersweet) and *Duboisia* (cork woods in New South Wales and Queensland). Severe poisoning may occur in children from the therapeutic use of atropine, homatropine and scopolamine. Symptoms develop promptly after ingestion. Dryness and burning of the mouth, thirst and difficulty in swallowing and talking occur. The vision is blurred, and photophobia is prominent. The skin is dry, hot and flushed. A rash occurs over the face, neck and upper part of the trunk, and desquamation may follow. In infants and small children the temperature may rise to as high as 107° F. The pupils are widely dilated; the pulse becomes weak and rapid, although no change may occur in infants; the blood pressure is elevated, and there may be palpitation, urinary urgency and difficult micturition. There may also be restlessness, excitability, confusion, weakness, muscular incoordination, giddiness and mild delirium, suggesting an acute psychosis. In infants the outstanding manifestations may be extreme abdominal distention, rapid respirations and distinct discomfort. Symptoms may persist for several hours or days, and the initial phase of excitement be followed by depression with circulatory collapse, respiratory failure and death. Diagnosis is often difficult; the rash, fever, tachycardia and delirium may suggest the onset of scarlet fever. The subcutaneous injection of 3 to 10 mg. of acetyl-beta methyl choline (Mechoyl) may be of diagnostic value. If salivation, sweating, lacrimation and intestinal hyperactivity do not occur after its injection, atropine poisoning may be present.

**Treatment.** Administration of water, milk or universal antidote should be followed by repeated gastric lavage and measures to reduce high fever. Short-acting barbiturates may control excitement and delirium.

**13. Barbiturates.** Five to six times the average hypnotic doses are toxic. The depressant action of barbiturates is due to an inhibition of the pyruvic-oxidase system. Symptomatology varies with the rapidity of action and the duration of the effect of the various compounds. Symptoms are somnolence, stupor, contracted pupils, coma, fall in blood pressure, respiratory and circulatory depression and occasionally pulmonary edema. In some instances there is hyperexcitability and confusion.

**Treatment.** The intensity of therapy should be adjusted to the degree of depression. Careful evaluation of the reflex responses and the cardiocirculatory and respiratory states should be made before institution of therapy. Short-acting barbiturates may produce death within an hour. Long-acting barbiturates may have depressing effects for four or five days. Lavage is indicated in all cases. Saline catharsis and stimulants may be indicated. Small repeated doses of caffeine, ephedrine, Coramine, Metrazol or strychnine may be of value. The repeated adminis-

tration of picrotoxin intravenously in the comatose patient may avoid further respiratory failure and lessen the depth of coma. The use of ephedrine and strychnine combined has been recommended. Intravenous glucose and saline solutions facilitate excretion of the drug and aid the liver in its detoxification. However, owing to the low ventilatory exchange, administration of large amounts of fluids too rapidly may lead to pulmonary edema. Maintenance of body temperature is of great importance. Blood transfusions, oxygen, carbon dioxide and artificial respiration may be necessary.

**14. Barium Salts.** The carbonate, hydroxide and chloride salts are used as pesticides; the sulfide, in depilatories. The barium ion produces stimulation of all muscle cells. After ingestion, tightness of the muscles of the face and neck, vomiting and diarrhea, muscular tremors, weakness, difficulty in breathing, cardiac irregularity, convulsions and death, from cardiac or respiratory failure, occur.

**Treatment.** Ten milliliters of 10 per cent sodium sulfate should be injected slowly intravenously every fifteen minutes until symptoms subside. Thirty grams of sodium sulfate in 250 ml. of water should be administered orally and repeated in one hour.

**15. Benzene Derivatives. Benzene.** Ingestion or inhalation of benzene fumes produces central nervous system depression. Principal clinical findings are coma and anemia. In mild poisoning dizziness, weakness, euphoria, headache, nausea, vomiting, tightness in the chest and staggering occur. In severe poisoning, visual blurring, tremors, shallow rapid respiration, paralysis, unconsciousness and convulsions ensue. Violent excitement or delirium may precede unconsciousness. Chronic poisoning from inhalation produces headache, anorexia, drowsiness, nervousness, pallor, anemia, petechiae and abnormal bleeding.

**TREATMENT.** Gastric lavage followed by catharsis. Great care should be taken to avoid aspiration. Epinephrine and ephedrine may induce ventricular fibrillation and should not be given.

**Naphthalene.** Common ingredient of moth repellents. Naphthalene produces hemolysis of red blood cells resulting in hemoglobinuria and hematuria. Liver necrosis may occur. Symptoms from acute poisoning following ingestion or inhalation are nausea, vomiting, diarrhea, oliguria, anemia, jaundice and pain on urination. Excitement, coma and convulsions may occur. Mental confusion and visual disturbances may occur after inhalation of fumes. Hemoglobinuria, albuminuria and casts may be present (pp. 264, 953).

**TREATMENT.** Gastric lavage followed by catharsis. Blood transfusions for anemia and exchange transfusion may be of value.

**Turpentine.** One-half ounce may cause fatal poisoning. Turpentine produces severe abdominal burning, nausea and vomiting. Diarrhea, pain on urination, unconsciousness, shallow respiration, bronchopneumonia and convulsions occur. Anemia, hemoglobinuria, hematuria, albuminuria and glycosuria may be present.

**TREATMENT.** Lavage should be performed carefully to avoid aspiration. Mineral oil may allay gastric irritation. General supportive measures and exchange transfusion are indicated.

**16. Bismuth.** Poisoning from injectible bismuth compounds is rare.

**Treatment.** See No. 9.

**17. Boric Acid and Borate Salts.** Boric acid may produce toxic symptoms when ingested or used as a wet dressing or as an ointment on large areas of injured skin, as in burns, diaper rashes or eczema. The mortality rate in infants is about 70 per cent. Excretion of boric acid from the body is slow, and cumulative action may occur. Symptoms of nausea, vomiting, abdominal pain and diarrhea occur. A maculopapular, urticarial or scarlatiniform rash occurs; the soles and palms are red. Desquamation follows in a few days. The mucous membranes are intensely congested. In infants signs of meningeal irritation may occur. Convulsions, delirium and coma follow. Albuminuria and azotemia may occur.

**Treatment** is symptomatic. Exchange transfusion may be lifesaving.

**18. Bromate.** Potassium bromate is used as a neutralizer in "cold wave" for the hair. Ingestion results in release of hydrogen bromate. Three ounces of the 3 per cent neutralizer solution may be fatal. Vomiting, diarrhea, abdominal pain, oliguria, lethargy, coma, convulsions and shock may occur.

**Treatment.** Gastric lavage followed by catharsis. One to 5 gm. of a 10 per cent solution of sodium thiosulfate intravenously is of value.

**19. Bromides.** Bromides are depressant to the central nervous system. Delirium and hallucinations may occur.

**Treatment.** The chloride ion, particularly ammonium chloride, may expedite elimination of bromide; 5 to 8 gm. per day in divided doses are recommended for adults. Intake of fluids should be generous.

**20. Cadmium.** Cadmium may be dissolved from plated pitchers and ice trays by such acid-containing foods as citrus fruit juices. Symptoms are manifest within approximately one-half hour and include nausea, vomiting, cramps and occasionally diarrhea, accompanied by general weakness. Recovery is usually rapid, within less than twenty-four hours.

**Treatment.** General supportive and sedative therapy is indicated. BAL will increase the concentration of cadmium in the urine, producing destructive tubular changes, and should not be used.

**21. Carbon Disulfide.** Inhalation of fumes or ingestion of the liquid produces central nervous system depression, with coma and terminal convulsions. Recovery may be followed by permanent damage to the central nervous system or the peripheral nerves.

**Treatment** is supportive.

**22. Carbon Monoxide.** The symptomatology of carbon monoxide is predominantly that of anoxia of varying degrees, with severe headache, weakness, dizziness, dimness of vision, nausea, vomiting, collapse, coma, intermittent convulsions and failing respiration. The symptoms are dependent upon the concentration of methemoglobin in the blood (see p. 1379). A cherry-red color is particularly noticeable on the lips and fingernails. Permanent residual damage to the central nervous system may occur if the anoxia is profound or prolonged.

**Treatment.** Carbon monoxide can be removed almost completely from the blood in thirty minutes if oxygen in high concentration with carbon dioxide

is administered. Artificial respiration should be continued until normal breathing is resumed.

23. **Chenopodium (Wormseed Oil).** Ten to twelve drops of oil of chenopodium may produce toxic symptoms and death. The symptoms are dizziness, tinnitus, impaired vision, vomiting, profound depression and unconsciousness and, in more severe cases, diarrhea, muscular twitchings and convulsions. Glycosuria has been observed. If the patient survives the acute symptoms, deafness may be present for a few days to a month. Damage to the liver is manifested by jaundice; injury to the kidney by hematuria and albuminuria.

**Treatment.** Saline catharsis, stimulants, oxygen and copious amounts of oral and parenteral fluids are required.

24. **Chlorobenzene Derivatives.** A large number of chlorobenzene derivatives are found in household solvents, insecticides, fungicides, sprays, waxes, and paint solvents and cleansers. The volatile halogenated hydrocarbons are very toxic. Chlorinated insecticides are less toxic and are usually only so by ingestion. However, they are fat soluble and often are marketed in a hydrocarbon vehicle.

25. **Chlorinated Insecticides.** These consist of the *chlorobenzene derivatives*: DDT, TDE, DFDT, Methoxychlor, Dimite, DMC, Neotran, Ovotran, Dilan; the *chlorinated camphenes* such as toxaphene; and the *indan derivatives*, Chlordane, heptachlor, Aldrin, Dieldrin, Endrin, and Diendrin. These are fat-soluble, highly stable insecticides used as dusts, wetting powders and solutions in organic solvents. Most toxic is Aldrin. Skin absorption of indan derivatives in organic solvents may be fatal within one hour. One to 3 gm. of these derivatives produces severe symptoms and may be fatal. Symptoms are stimulation of the central nervous system such as hyperexcitability, tremors, ataxia, and convulsions beginning within thirty minutes to six hours. Central nervous system depression with respiratory failure ensues. Recovery is more likely if convulsions are delayed.

**Treatment.** Gastric lavage with large volumes of water followed by catharsis. The skin should be scrubbed with soap and water to remove contamination. Convulsions may be controlled with barbiturates, intramuscularly or intravenously. Stimulants should be avoided, and epinephrine is contraindicated.

26. **Chromates.** Chromate salts are highly irritating and destructive to tissues. After ingestion, dizziness, intense thirst, abdominal pain, vomiting, shock and oliguria or anuria occur. Chronic poisoning produces an eczematous dermatitis.

**Treatment.** Gastric lavage followed by catharsis and supportive fluid therapy.

27. **Cleaning Solutions.** Chemical constituents of various types: *Automobile paint cleaners* (free alkali, alkali salts, detergents, soap); *brush cleaners* (aromatics, halogenated hydrocarbons, alcohols, paraffins); *carbon cleaners* (aromatics, halogenated hydrocarbons, alcohols, paraffins); *dry cleaners for clothes* (halogenated hydrocarbons, alcohols, paraffins); *glass and furniture cleaners* (ammonium hydroxide, methyl alcohol, sodium hydroxide, detergents, soap); *grease removers (degreasers)* (usually contain only paraffins such as kerosene, hydrocarbons, gasoline or free alkali, alkali and salts, deter-

gents, soap); *gun cleaners* (nitranilines); *metal cleaners* (nitric acid, sulfuric acid, cyanides); *silver polish* (silver nitrate, free alkali, alkali salts); *radiator (automobile) cleaning compounds* (free alkali, alkali salts, detergents, soap); *straw hat cleaners* (oxalic acid); *toilet and drain cleaners* (hydrochloric acid, sulfuric acid, sodium sulfate, sodium hydroxide, sodium carbonate); *typewriter cleaners* (aromatics, halogenated hydrocarbons, and paraffins).

28. **Cocaine (Butocaine, Tutocaine, Methycaine, Nupercaine, etc.).** Toxicity develops quickly after oral ingestion, hypodermic injection or local application of cocaine or its derivatives to mucous membranes. Symptoms are excitability, restlessness, confusion, delirium, hyperactive reflexes, rapid pulse, elevated blood pressure, widely dilated pupils and exophthalmos. Nausea and vomiting are due to central stimulation. Death is preceded by Cheyne-Stokes respiration and convulsions.

**Treatment.** See No. 72. The patient should be catheterized to prevent reabsorption of cocaine from the bladder.

29. **Coniine.** Toxic component of the parsley family. These include poison hemlock (*Conium maculatum*) and water hemlock (*Cicuta maculata* and other *Cicuta* species). Coniine produces peripheral muscular paralysis similar to that of curare. Increasing muscular weakness, paralysis and respiratory failure occur.

**Treatment.** Gastric lavage followed by catharsis, artificial respiration and oxygen.

30. **Cosmetics. Deodorants** (aluminum salts); *depilatories* (barium or sodium sulfide); *freckle removers* (bichloride of mercury, bismuth, ammoniated mercury); *skin foods and creams* (mercury, salicylic acid); *hair sprays* (synthetic and natural resins). Inhalation produces diffuse pulmonary granulomatous lesions.

31. **Cough Medicines,** commonly contained agents of: antibiotics, antihistamines, chloroform, codeine, ephedrine sulfate and related compounds, opium derivatives, barbitol derivatives.

32. **Cyanide.** Acute cyanide poisoning from ingestion of the salt or inhalation of hydrocyanic acid produces symptoms of giddiness, hyperpnea, headache, palpitation, cyanosis, unconsciousness and asphyxial convulsions resulting in death within a few seconds to minutes. Death may be delayed as long as three hours. The odor of oil of bitter almonds on the breath is diagnostic. Symptoms may be confused with those of nitrobenzene poisoning, which produces methemoglobinemia with cyanosis.

**Treatment.** Specific, prompt treatment is sometimes successful. Poisoning following inhalation of cyanide gas should be treated with amyl nitrite inhalation immediately and repeated every five minutes unless blood pressure falls. Clothing should be removed and the skin washed with soap and water. Artificial respiration and oxygen should be given. Ten milliliters of 3 per cent sodium nitrite solution should be administered intravenously at a rate of 2.5 to 5 ml. per minute; if the systolic blood pressure falls below 80 mm. of mercury, it should be stopped. After administration of sodium nitrite, 50 ml. of a 25 per cent solution of sodium thiosulfate should be given intravenously at a rate of 2.5 to 5 ml. per minute. The sodium nitrite produces methemo-

globin, which can combine with the cyanide ion to form cyanmethemoglobin. The sodium thiosulfate is injected slowly to convert the cyanide released by dissociation of cyanmethemoglobin to thiocyanate. One per cent solution of methylene blue intravenously may be of some value.

33. **Daphne (Daphnin).** In bright red berries and all parts of the plants. Ingestion of the plant produces abdominal pain, vomiting, bloody diarrhea, weakness, convulsions and renal damage.

34. **Darnel.** The seeds contain temuline. Flour may be contaminated with darnel, and bread made with such flour may produce vertigo, staggering, vomiting, visual disturbances, burning pain in the mouth and prostration.

35. **Detergents.** *Cationic:* Phemerol (benzethonium chloride), Zephiran (benzalkonium chloride), Diaparene (benzethonium chloride) and Ceepryn chloride (cetyl pyridinium chloride) destroy bacteria and are used as skin cleansers, on surgical instruments, cooking equipment, sick room supplies and diapers. Ingestion of 1 to 3 gm. may be fatal. Symptoms are vomiting, collapse and coma with death within a few hours.

**Treatment.** Gastric lavage should be done immediately and thoroughly, using ordinary soap solutions.

36. **Digitalis.** Poisoning occurs most commonly from medicinal preparations. Digitalis glucosides, however, are contained in a large number of plants. Symptoms of poisoning occur within one-half to six hours after ingestion of large doses and are usually initiated by nausea and vomiting of reflex origin. Arrhythmias and bradycardia may be present. Headache, drowsiness and coma have been described. Death occurs from ventricular fibrillation. Electrocardiographic changes are present in about 66 per cent of overt poisonings. Overdosage of digitalis during therapeutic administration of the drug is evident initially by the appearance of anorexia, soon followed by nausea and vomiting. These symptoms may become manifest over a period of several days; if large doses have been given, the vomiting may occur without preceding episodes of nausea. Excessive salivation and diarrhea, often accompanied by abdominal discomfort and pain, may be present. Cardiac arrhythmias, particularly extrasystoles of ventricular origin, and paroxysmal tachycardia may also occur. Bradycardia resulting from the direct action of digitalis on the sinoatrial pacemaker or the atrioventricular conduction system may follow. Death may occur from ventricular fibrillation. Headaches, fatigue, malaise, blurred vision, drowsiness and mental symptoms of confusion, disorientation and even convulsions may occur.

**Treatment.** When poisoning is due to accidental ingestion, prompt gastric lavage is indicated, but when it results from continued overdosage, lavage will not be helpful. Adequate fluids should be given to facilitate excretion, but diuretics may be dangerous, owing to excessive extraction of digitalis from the tissues. Absolute bed rest should be enforced until clinical and electrocardiographic evidence of toxicity to the heart has disappeared. Nothing more is indicated if the pulse is slow or even if there is a heart block, but when there is ventricular tachycardia, emergency treatment is required to avoid ventricular fibrillation. Five to 10 ml. of a 10 per

cent solution of magnesium sulfate should be administered intravenously for an immediate effect and should be followed by oral administration of quinidine sulfate. One to 2 grains should be given every two to three hours throughout the twenty-four hour-period for two or three days. If the child is vomiting, intramuscular injection of quinidine is required.

37. **Dinitro-ortho-cresol.** These derivatives of phenol and cresol are used as insecticides and herbicides. They inhibit phosphate synthesis which results in increased cellular respiration. *Acute poisoning* from skin contamination, ingestion or inhalation produces fever, prostration, thirst, nausea and vomiting, excessive perspiration and difficulty in breathing. Later anoxia, cyanosis, muscular tremors and coma occur. *Chronic poisoning* produces skin eruption, neuritis, hepatic and renal damage and injury to the bone marrow.

**Treatment.** Thorough lavage with saturated bicarbonate solution should be done, followed by catharsis. Control of body temperature, oxygen and support of respiration are required. Intravenous glucose to support increased metabolic activity is advisable.

38. **Ergot.** Ergot is present in certain proprietary mixtures used as abortifacients. Rye flour may be contaminated with ergot fungus. Acute poisoning from ingestion, injection or application to mucous membranes produces vomiting, diarrhea, dizziness, unstable blood pressure, weak pulse, dyspnea, convulsions and loss of consciousness. The dose required to produce an abortion may cause death.

**Treatment.** Absorption may be delayed by giving water, milk or universal antidote; gastric lavage should follow. Saline catharsis is indicated. Sedation should be prescribed for convulsions.

39. **Esters, Aldehydes and Ethers.** *Dimethylsulfate* is caustic to mucous membranes of the eyes, nose, throat and lungs. Inhalation produces pulmonary edema. Symptoms of intense irritation and erythema of the eyes, severe lacrimation, and chemosis occur after inhalation, skin absorption or ingestion. Cough and edema of the tongue, lips, larynx and lungs follow. The corrosive action is similar to that of sulfuric acid; dimethylsulfate in the presence of water hydrolyzes to methyl alcohol and sulfuric acid.

**TREATMENT.** Copious washing of contaminated mucous membranes and skin surfaces.

*Tri-ortho-cresyl-phosphate.* The ortho form is toxic. The agent is used as a lubricant, fireproofing and plasticizer in coating plastics. Food may become contaminated. Symptoms are due to inhibition of cholinesterase, producing weakness and paralysis of distal muscles. Death from respiratory paralysis may occur. Symptoms may be delayed several weeks, and degenerative changes in the muscles and spinal cord may be observed at autopsy.

**TREATMENT.** Gastric lavage followed by saline cathartics and support of respiration are necessary.

*Acetaldehyde, metaldehyde, and paraldehyde.* Paraldehyde and metaldehyde are thought to degrade to acetaldehyde in the body. Toxicity is related to limited oxidation of acetaldehyde. Acetaldehyde vapors cause severe irritation of mucous membranes, cough, pulmonary edema and narcosis. Ingestion causes nausea, vomiting, diarrhea, narcosis and re-

spiratory failure. Paraldehyde produces deep and prolonged sleep, and metaldehyde causes nausea, severe vomiting, abdominal pain, muscular rigidity, convulsions, and death from respiratory failure.

**Treatment.** Copious washing of material from mucous membranes and gastric lavage, followed by saline catharsis. Artificial respiration is necessary.

40. **Favism.** Ingestion of *Vicia fava* (broad beans, horsebean) or inhalation of the dust of such beans may produce, particularly in children, symptoms of poisoning. The mechanism by which hemolysis is brought about is related to a defect in the glucose-6-phosphate dehydrogenase system of the erythrocytes (pp. 264, 953).

**Treatment.** Severe hemolytic anemia may require transfusions. A corticosteroid should be given.

41. **Fish Poisoning.** Several varieties of fish contain poisons within their bodies throughout the year. Others are poisonous only during the spawning season. Fish may also become contaminated with pathogenic or saprophytic organisms (*Salmonella*, typhoid, staphylococci). Fish poisoning (ichthyotoxism) may be due to eating of Tetraodontidae (puffers) or of the Diodontidae (porcupine fish). The Clupeidae (herring family), particularly *Clupea thrissa* and *venonosa*, and the Scarus (parrot fish) may also contain poisons. An alkaloid-like substance, fugin, present in puffers and certain other fish produces headaches, restlessness, salivation, vomiting, paralysis, cyanosis, and dilatation of the pupils. Death occurs from dyspnea and anoxia. Some varieties of sturgeon (*Acipenseridae*), pike (*Esocidae*) and barbel (species of *Barbus*) have poisons in their reproductive organs during their spawning season.

42. **Fluoride.** Fluoride salts and compounds are rapidly absorbed and slowly excreted. They are protoplasmic poisons inhibiting cellular enzyme action. Fluoride poisoning produces severe nausea and vomiting, diarrhea and collapse within a few hours. If patients are ill over a longer time, there are excessive salivation, dilated pupils, steady pulse, shallow unlabored respirations and weak heart tones. Cyanosis due to fluoromethemoglobinemia is not uncommon. Occasionally there is paralysis of the muscles of deglutition, carpopedal spasm and muscular spasm of the extremities.

**Treatment.** Immediate lavage with calcium chloride prevents absorption by forming insoluble calcium fluoride; if calcium chloride is not available, copious quantities of milk may be given after lavage with warm water. Intravenous calcium chloride or calcium gluconate may also be of value. Treatment is largely symptomatic and supportive. Exchange transfusion may be indicated.

43. **Fluoroacetate.** Fluoroacetate blocks aerobic metabolism at the citric acid level of the Krebs' cycle. Very small doses may be fatal for children, and 300 mg. may be fatal for an adult. Symptoms are prompt vomiting, apprehension, stupor and generalized convulsions occurring within six hours. Carpopedal spasm may be present. Respiratory and cardiac irregularity and failure may occur.

**Treatment.** Lavage and catharsis are indicated. Cardiac and central nervous system symptoms may be modified by administration of 0.1 to 0.5 ml. per kilogram of acetate such as glycerol monoacetate

injected intramuscularly at hourly intervals. An overdose of monoacetate may lead to nervous system depression and death. Calcium may be of value for tetanic manifestations. Digitalization for cardiac irregularities is of little value. Fluid therapy should be cautious because of cardiac and respiratory stress.

44. **Formaldehyde.** Formaldehyde is a general protoplasmic poison. It is a protein precipitant which preserves and hardens tissues. The gas is now infrequently used as a fumigant. Exposure to the gas produces intense conjunctivitis and irritation of the respiratory tract, often with resulting coryza, bronchitis and pneumonia. Ingestion of formaldehyde is followed by severe irritation of the mucosa of the mouth, throat and intestinal tract, intense abdominal pain, vomiting and diarrhea. Formaldehyde depresses the central nervous system, producing vertigo, depression and coma. Convulsions are rare. Oxidation of formaldehyde by the body produces formic acid and a resultant acidosis.

**Treatment.** Lavage should be carried out with dilute ammonia water (0.2 per cent) or egg albumen in water. The acidosis and impending shock must be treated, and respiratory stimulants may be indicated.

45. **Hydrocarbons (Kerosene, Solvent Distillate and Gasoline).** Ingestion of more than 10 ml. of these petroleum distillates increases the toxicity tremendously. These agents produce over 200 deaths a year in children in the United States. Within fifteen minutes to one hour after ingestion of most hydrocarbons, symptoms of nausea, vomiting, cough and central nervous system stimulation may occur. Kerosene produces a gastroenteritis; gasoline usually does not. The hydrocarbons are readily absorbed and are excreted by the lungs. Vertigo, fever, drowsiness and confusion result. Methemoglobin formation is common. Bronchitis or pneumonia from aspiration of hydrocarbons may develop within the first twenty-four hours or be delayed. Inhalation of gasoline produces an intense burning sensation in the throat and lungs within a few minutes after exposure, and bronchopneumonia may develop rapidly.

**Treatment.** It is advisable not to induce vomiting in hydrocarbon poisoning, since the frequency of pulmonary complications is thought to be greater. Lavage carefully done is advisable, extreme caution being taken to avoid aspiration. When only small amounts have been taken, saline cathartics are indicated, and lavage is usually not necessary. General supportive measures, oxygen, transfusion for methemoglobinemia, and carbon dioxide stimulation may prevent development of secondary bacterial pneumonia.

46. **Hydrocarbons (Halogenated).** *Carbon tetrachloride.* A nonflammable volatile solvent, used as a cleaner in floor waxes and in fire extinguishers. Ingestion of 3 to 5 ml. may be fatal. Symptoms occur quickly after inhalation or ingestion or from skin absorption. Signs of central nervous system depression, such as dizziness, confusion and unconsciousness, occur. Respiratory and cardiac irregularity and collapse occur. Recovery may be followed in a few days or up to two weeks by evidence of liver or kidney damage.

**Treatment.** General supportive measures, artificial respiration and gastric lavage followed by

catharsis. A high carbohydrate intake is advisable. Epinephrine and ephedrine are contraindicated because they may induce ventricular fibrillation.

**Methyl bromate, methyl chloride.** These gases are used as refrigerants and fumigants. They may be present with carbon tetrachloride in fire extinguishers. Toxic tissue effects are similar to those of carbon tetrachloride except that bronchopneumonia and pulmonary edema are more common. The substances are metabolized to methyl alcohol and hydrobromic or hydrochloric acids in the body. Acute poisoning from inhalation, ingestion or skin absorption produces nausea, vomiting, vertigo, weakness, oliguria, drowsiness, hypotension, coma and convulsions. Pulmonary edema develops and progresses for several hours. In mild poisoning the symptoms may not develop for several hours. Vesiculation of the skin may be present where contact has occurred.

**TREATMENT** as for carbon tetrachloride with special measures for pulmonary edema.

**Trichloroethane.** This solvent may be present in rug, wall and clothing cleaners. Symptoms are those of severe depression of the central nervous system followed by evidence of myocardial, hepatic and renal injury. Recovery may be rapid after removal of the poison; late jaundice is uncommon.

**TREATMENT** as for carbon tetrachloride.

**Tetrachloroethane.** Occasionally present in household cleaners, it is the most poisonous of the halogenated hydrocarbons. Death from acute poisoning may occur quickly and leave evidence of congestion of the lungs, kidneys, brain and gastrointestinal tract. Symptoms of acute poisoning are intense irritation of the eyes and nose, headache, nausea, cyanosis and central nervous system depression appearing over a period of one to four hours. After recovery, evidence of jaundice, anuria and uremia may be present.

**TREATMENT** as for carbon tetrachloride.

**Ethylene chlorohydrin.** Used as a cleaning solvent and also to speed the germination of seeds and potatoes. Ingestion results in pulmonary edema, vascular damage, direct toxic action on cardiac muscle and depression of the nervous system followed by damage to the liver and kidneys. Symptoms are those of respiratory and circulatory failure.

**Chlorinated naphthalene and chlorinated diphenyl** (Halowax, Arochlor). These substances are used as high temperature dielectrics for electrical equipment. Chronic poisoning produces acneiform lesions, drowsiness, hepatic injury and coma.

**TREATMENT** as for carbon tetrachloride.

47. **Iodine.** The toxic effects of iodine are due largely to its corrosive action on the gastrointestinal tract. Iodine is highly reactive and combines readily with starch, proteins and fats in the digestive tract. Ingestion is followed by reflex vomiting, burning abdominal pain and bloody diarrhea. Shock may result from fluid loss, and death may occur in one to forty-eight hours. The diagnosis is obvious from the brownish staining of the mucous membrane and the blue color of the vomitus or lavaged material.

**Treatment.** Lavage with soluble starch solutions or a combination of sodium thiosulfate (5 per cent) and albumen (egg white). Intravenous fluid is indicated to avert dehydration and shock.

48. **Iron Salts (Ferrous Sulfate).** As few as ten to fifteen ferrous sulfate candy-coated tablets (5

grains) may be fatal. Symptoms may occur thirty to sixty minutes after ingestion. Danger may exist for at least twenty-four hours. Acute gastroenteritis, vomiting, diarrhea, dehydration, collapse, and coma ending in death may occur. A severe acidosis may also be present. The diarrhea may be initially watery, becoming bloody and then tarry. Approximately 50 per cent of the reported cases have been fatal.

**Treatment.** Lavage with sodium bicarbonate to produce insoluble ferrous carbonate. Sodium bicarbonate should be left in the stomach along with magnesium sulfate for catharsis. BAL is probably of little value. Management of the dehydration, acidosis and shock is imperative.

49. **Lye and Corrosive Alkalis.** Potassium hydroxide, sodium hydroxide, potassium carbonate, sodium carbonate, sodium phosphate and sodium silicate are corrosive alkalis. Ammonia and ammonia hydroxide may also produce corrosive tissue actions. These substances produce intense local irritation of the mouth, pharynx, esophagus and stomach. Perforation of the esophageal or gastric wall may occur within relatively few hours. Recovery is invariably associated with scarring of the esophagus and with stenosis unless proper precautions are taken. Ingestion of alkali produces severe pain, vomiting, diarrhea and collapse.

**Treatment.** Lavage with copious volumes of dilute vinegar, lemon juice or weak acids. Instillation of several ounces of olive oil or flour paste after lavage may be of value. Vomiting should not be induced in corrosive alkali poisoning. If an hour or more has elapsed since ingestion, lavage should be avoided, and only aspiration of the thick accumulated secretions from the pharynx should be performed. Small quantities of olive oil should be given at frequent intervals. A liquid diet and parenteral fluids are necessary, owing to the dysphagia. Stricture of the esophagus may at times be avoided by early dilation (see p. 643).

50. **Meadow Saffron (Colchicum Autumnale).** Colchicine is present in the leaves and seeds, which may be eaten in salad. Symptoms occur three to six hours after ingestion, with abdominal discomfort and violent, uncontrollable vomiting and purging. Bloody diarrhea and collapse from exhaustion and dehydration follow.

**Treatment.** Lavage followed by saline catharsis. Dehydration and shock must be treated.

51. **Mercury.** Mercury, usually ingested by children in the form of mercury bichloride tablets, is a protein precipitant (see also Acrodynia, p. 1398). Mercury produces severe, painful lesions of an ashen-gray color on the mucous membranes of the mouth, throat, stomach and intestines. In the stomach it causes intense gastric pain and vomiting within a short time. The prognosis is improved if the interval between ingestion and vomiting is short and if there is extensive vomiting. If mercury reaches the small intestine, a severe, profuse, bloody diarrhea occurs. Mucosal shreds may be passed. Profound shock due to circulatory collapse soon follows. If the patient survives the acute phase, severe symptoms of systemic toxicity appear within a few hours and last for many days. Damage to the renal capillaries and tubules is responsible for the albuminuria, hematuria and excretion of casts. Diuresis sometimes

occurs initially, owing to the faulty reabsorption of water by damaged renal tubules, but eventually there is oliguria and anuria. Widespread capillary hemorrhages and transudation of protein and fluid from the blood stream result in circulatory failure and shock.

**Treatment.** Immediate and repeated lavage with raw white of egg or milk provides protein for precipitation by the mercury. BAL is particularly effective. It should be given intramuscularly as promptly as possible, since experimentally it is less effective after extensive tissue damage has occurred. The initial dose should be 5 mg. per kilogram, followed in one or two hours by a dose of 2.5 mg. per kilogram. After two to four hours the latter dose should be repeated, and in severe cases a fourth one should be administered within the first twelve hours after the first injection. On the second day two injections may be given, each of 2.5 mg. per kilogram. On the third day only one dose of 2.5 mg. per kilogram is necessary.

Sodium formaldehyde sulfoxalate is said to reduce soluble mercuric salts to the insoluble monovalent (mercurous) form; the stomach is lavaged with 250 ml. of a 5 per cent solution. From 100 to 250 ml., depending upon the age of the child, are then left in the stomach. This procedure is followed by intravenous administration of 50 to 200 ml. of a 10 per cent solution. Lavage with 10 ml. of 10 per cent sodium hypophosphite containing 2.5 ml. of hydrogen peroxide and diluted to 100 ml. is also of value. Sodium hyposulfite, chalk, freshly precipitated ferrous hydroxide, milk of magnesia or starch paste may also be used. After lavage, attention should be given to maintenance of a normal composition of the body fluids; one-half isotonic Ringer's or polyionic solutions should be given parenterally to maintain body fluids and to produce a copious diuresis in order to protect the kidneys from high concentrations of mercury. Such therapy should be continued unless edema and oliguria develop. Prognosis depends upon the amount of mercury taken, the interval between ingestion and lavage, and the degree and duration of kidney damage. Too much stress cannot be placed upon the importance of the immediate removal of ingested mercury, since absorption is rapid.

52. **Milk sickness**, or "trembles," occurs in animals from eating the rayless goldenrod (*Tremetol*) or the white snakeroot which contain toxic substances. In man the ingestion of milk products or the flesh of poisoned animals produces nausea, vomiting and constipation. The tongue becomes dark red and tremulous; the cheeks are flushed and the lips red. Abdominal pain and muscular weakness may occur. Deaths have been reported.

53. **Monk's Hood Root (Wolfsbane) and Larkspur.** The fresh leaves and roots of these plants contain aconite. Absorption occurs readily and may result in instantaneous death, probably from paralysis of the heart. Symptoms are tingling in the mouth, stomach and skin (most important diagnostic feature), excessive salivation, nausea, vomiting and diarrhea. The pulse is slow and feeble, and there are dyspnea, weakness, impaired speech, unconsciousness and convulsions. Death usually follows in two to six hours.

**Treatment.** Prompt lavage with potassium per

manganate, 1:1000, should be followed by saline catharsis; artificial respiration, oxygen and cardiac and respiratory stimulants should be used when indicated.

54. **Mountain Laurel (Andromedotoxin).** Ingestion of young shoots and leaves produces salivation, lacrimation and nasal discharge. Vomiting, convulsions, slowing of pulse, lowering of blood pressure, and paralysis may occur.

**Treatment.** See No. 76.

55. **Mushroom Amanita Muscaria (Mycetismus Nervosus, Fly Amanita).** This plant contains muscarine and produces severe gastrointestinal symptoms soon after ingestion, followed shortly by profuse perspiration, salivation, miosis, delirium, hallucinations, convulsions and coma. The pharmacologic action of muscarine on smooth muscle and glands is similar to that of acetylcholine. Mild degrees of intoxication occur, and there may be individual susceptibility.

**TREATMENT.** Lavage followed by saline catharsis is imperative. Atropine given hypodermically is of value.

**Amanita phalloides (Mycetismus choleriformis, death cup, destroying angel).** This plant, which is extremely toxic, contains several toxins not completely identified; the mortality in human poisoning is 60 to 100 per cent. Symptoms may be delayed six to fifteen hours after ingestion, when there are sudden severe abdominal cramps followed by vomiting and diarrhea, with mucous and bloody stools. The intoxication is prolonged, and jaundice develops in two to three days, indicating severe degenerative changes in the liver. The kidney is involved, and direct toxic action of the heart may result in cardiac failure and death within five to eight days.

**TREATMENT.** Immediate lavage, enemas and saline catharsis are indicated. Dehydration and shock must be treated. The degree of toxic tissue changes may be ameliorated by large amounts of glucose, plasma and blood intravenously.

56. **Nicotine.** The toxicity and rapidity of action of nicotine are comparable to those of cyanide. The local caustic action produces nausea, salivation, abdominal pain, vomiting and diarrhea. After absorption there are headache, dizziness, visual and hearing disturbances, mental confusion and intense weakness, and death may follow within a few minutes. Respiratory stimulation, elevated blood pressure and slow pulse are also early manifestations. Later there are pinpoint pupils and a curare-like action of the skeletal and respiratory muscles. Respiratory and circulatory failure is followed by convulsions and death.

**Treatment.** Lavage with tannic acid, strong coffee or tea for ingested poison. Nicotine on the skin should be thoroughly washed off. Owing to the rapid destruction of nicotine in the body, death can be averted if primary attention is directed toward prevention of respiratory failure. Artificial respiration and oxygen should be continued until normal breathing is resumed or the heart has stopped. Epinephrine, caffeine and Coramine are not ordinarily indicated unless respiratory failure develops.

57. **Nitrites.** Medications, such as bismuth subnitrite, amyl nitrite, sodium nitrite or spirit of glyceryl trinitrate, may be taken accidentally by children. Therapeutic use of bismuth subnitrite may

result in formation of nitrites by bacterial decomposition in the intestines. Cyanosis in infants due to poisoning with water containing nitrates has been described. Water seeping from barnyards heavily laden with bacteria and dissolved nitrogenous materials may become increasingly purified by passage through the soil. However, certain soil bacteria oxidize the ammonia and other nitrogenous compounds to nitrates. The solution of nitrates, free of coli organisms, may enter subsurface channels leading directly into wells used for drinking purposes. Ingestion of such water in milk formulas may result in conversion of the nitrates to nitrites by gastrointestinal organisms. Flushing of the skin, fall in blood pressure, severe methemoglobinemia, cyanosis and dyspnea develop. Syncope and respiratory failure may occur.

**Treatment.** Lavage should be followed by saline catharsis, particularly in bismuth subnitrite poisoning. When syncope occurs, epinephrine and other vasopressor agents should be avoided. A deep Trendelenburg position of the body and passive movements of extremities may facilitate return of venous blood to the heart. Transfusions and oxygen are indicated for the methemoglobinemia, and methylene blue is of value.

58. **Nutmeg.** One teaspoonful of powdered nutmeg may produce severe toxic symptoms. Narcosis with periods of delirium and excitability may occur within one to six hours.

59. **Oils.** Most of the nonvolatile hydrocarbon oils are nontoxic. Ingestion, however, may be associated with vomiting and aspiration into the lungs. Pulmonary complications are more intense with vegetable and animal oils.

**Treatment.** Emetics should not be given. Lavage should be done with care, avoiding emesis.

60. **Opiates.** Several natural alkaloids of opium, particularly morphine and codeine, and some synthetic narcotics cause toxic effects in infants and children. Poisoning occurs as a result of excessive therapeutic administration or from accidental ingestion. It has been stated that infants and children are more susceptible to the actions of the opiates, but there is reason to doubt this statement. Manifestations of opiate poisoning are those of central nervous system depression. Somnolence, coma and respiratory depression, often severe, may be noted. Pinpoint pupils, although observed, are not diagnostic of opiate poisoning.

**Treatment.** Prompt, vigorous treatment is mandatory and should be directed to the prevention of anoxia and further respiratory depression. Oxygen and artificial respiration may be indicated, and the airway must be kept patent.

Two specific opiate antagonists are available: N-allylnormorphine (Nalline) and L-3-hydroxy-N-allylmorphinan tartrate (Lorfan). Both drugs have specific antagonistic actions against all opiates, natural and synthetic. They are ineffective against other central nervous system depressants such as phenobarbital, and, in fact, will produce the toxic effects of opiates if used in situations other than opiate poisoning. The drugs should be administered intravenously as rapidly as possible. The recommended intravenous dose of Nalline is 0.025 mg. per kilogram; the dose of Lorfan is approximately one twentieth of the above. The same dose of either

drug may be repeated once or twice as needed at intervals of twenty minutes, the approximate duration of effect of each drug.

61. **Oxalates and Oxalic Acid.** Local irritation is produced by ingested oxalic acid. Both the acid and its salts are rapidly absorbed, and death occurs quickly. Absorbed oxalate combines with the ionized calcium of the blood, producing hypocalcemia leading to muscular twitchings, laryngospasm, tetany and convulsions. The heart stops beating in diastole.

**Treatment.** Lavage with 0.1 per cent potassium permanganate should be followed by a 5 per cent calcium chloride, chalk or lime solution. Calcium gluconate or calcium chloride intravenously is of value if signs of tetany are present.

62. **Phenols (Carbolic Acid, Cresol, Creosote, Creolin, Lysol, Resorcinol and Pyrogallol).** Phenol may produce symptoms leading to death within a few minutes, dependent upon the surface from which the substance is absorbed. Death (lethal dose is 8 to 15 gm.) usually occurs within twenty-four hours from respiratory failure. Initial symptoms are severe, painful local corrosion of mucous membranes and severe vomiting. Widespread capillary damage, medullary depression and shock occur quickly. Fleeting excitement may occur, followed by unconsciousness. Other symptoms are low blood pressure, cold sweat, hypothermia, oliguria, albuminuria and hemoglobinuria.

**Treatment.** The drug must be removed promptly before absorption occurs. Lavage with olive oil or other vegetable oils provides a solvent for the phenol. Neither alcohol nor mineral oil should be used; alcohol facilitates absorption, and mineral oil is a poor solvent for phenol. After lavage several ounces of olive oil should be left in the stomach. Copious parenteral fluid administration should be instituted to protect the kidneys. The acidosis responds promptly to intravenous administration of sodium bicarbonate or sixth-normal sodium lactate. Artificial respiration should be performed when respiratory failure occurs.

63. **Phenolphthalein.** Phenolphthalein is present in many candy cathartics (Analax, Ex-lax, Phenolax and cathartic chewing gum). Children have been known to eat more than a box of the tablets. Apparently, large amounts of phenolphthalein can be ingested without serious results. The range of toxic doses is not known. Severe toxic actions may be manifest in hypersusceptible persons. A violent cathartic action results several hours later. A bright red skin eruption and swelling of the eyelids may occur. High fever, meningismus, hemiplegia, albuminuria, oliguria, and respiratory and cardiac failure have been attributed to phenolphthalein poisoning.

**Treatment.** General supportive treatment is indicated. If violent catharsis is present, and dehydration and acidosis ensue, parenteral fluid therapy should be administered. Diagnosis may be established easily by the development of a pink color in lavaged material, stool or urine on the addition of alkali.

64. **Phosphorus, Inorganic.** Red phosphorus is nonabsorbable and therefore nonpoisonous. Yellow phosphorus is highly poisonous, producing severe tissue destruction. Yellow or white phosphorus is used in rodent and insect poisons, in fireworks and

in the manufacture of fertilizer. Zinc phosphide used in rat poisons releases phosphine on contact with water. Symptoms of acute poisoning occur within one to two hours. Nausea, vomiting, diarrhea, and a garlic odor of the breath and excreta may be noted. Coma may occur within twenty-four to forty-eight hours. If recovery from the acute phase occurs, symptoms may return in one to two days with nausea, vomiting, diarrhea, large tender liver, jaundice, shock, oliguria and multiple hemorrhages. Phosphorus causes second- to third-degree burns on contact with the skin.

**Treatment.** Acute poisoning should be treated by gastric lavage with large amounts of 0.2 per cent copper sulfate. Potassium permanganate, 1:1000, or 2 per cent hydrogen peroxide tends to convert elemental phosphorus to harmless oxidation products. Phosphorus is soluble in mineral oil; therefore the instillation of 100 to 200 cc. of mineral oil after lavage may facilitate its elimination. Supportive measures include treatment for dehydration, acidosis and shock, and subsequently a high carbohydrate diet and amino acids, orally or parenterally to protect the liver from serious injury. When there has been liver damage, such treatment should be continued until there is evidence that function has returned.

**65. Phosphorus, Organic.** Phosphate ester insecticides should never be used in homes. All are anticholinesterase compounds. There are three major types of organic phosphate insecticides: the nitrophenyl thiophosphates, the alkyl pyrophosphates, and the phosphoramides. They vary in distribution of tissue and in duration of action. The phosphoramide compounds have no cerebral action, acting entirely by peripheral inhibition of cholinesterase. The alkyl pyrophosphates are rapidly hydrolyzed in the body to nontoxic metabolites. The thiophosphates are more stable and are detoxified slowly. Most of these compounds are several times more toxic than nicotine. One drop of parathion in the eye may be fatal. Malathion is probably the least toxic. One gram, however, may be fatal. Symptoms are prompt within thirty minutes, and may continue for twenty-four to forty-eight hours. They consist of increased secretions (such as sweat, saliva, tears and bronchial fluids), nausea, vomiting, diarrhea, miosis, blurred vision, bronchiolar spasms and pulmonary edema. Ataxia, vertigo, tremors, muscular weakness, fibrillation, fasciculation, finger and mouth twitching, muscular paralysis, cyanosis, dyspnea, chest constriction, stupor, coma and convulsions may also occur.

**Treatment.** Artificial respiration to maintain ventilatory exchange is indicated. Wash all insecticide off the skin and mucous membranes. Atropine in effective doses should be given hourly if necessary. Pupillary dilatation and decreasing secretions are a measure of atropine effect. Magnesium sulfate intravenously may be of value. Morphine, barbiturates and respiratory depressants should be avoided.

**66. Rotenone (Derris Root, Cubeb).** An insecticide frequently mixed with pyrethrum powder. The lethal dose is probably large. Solutions or powder may be absorbed from the lungs or gastrointestinal tract. Symptoms are predominantly respiratory. There is an acceleration in the respiratory rate followed by a decrease; death occurs from respiratory failure. Evidences of gastric irritation such as nausea

and vomiting may occur. Symptoms occur promptly within a few minutes to an hour.

**Treatment.** Lavage, catharsis and supportive measures.

**67. Salicylates (Methyl Salicylate, Salicylic Acid, Sodium Salicylate, Acetyl Salicylic Acid and a Variety of Proprietary Ointments and Medications Containing either Salicylic Acid or Salicylates).** Prolonged excessive or accidental ingestion of salicylates may result in severe poisoning. Absorption may occur from the mouth, gastrointestinal tract and the skin. The peak action occurs about four hours after a single toxic dose and may last longer than eighteen hours. Rarely, effects of poisoning may persist for ten days. Methyl salicylate and salicylic acid produce symptoms rapidly. Both cause severe gastrointestinal irritation with nausea and vomiting. Local painful lesions are caused by the caustic action of the acid. Intoxication may occur from the use of salicylic acid powder or ointment on large, open, weeping skin lesions. The toxic dose is usually in excess of 0.15 gm. per kilogram of body weight.

Initial symptoms in man, as well as those produced in experimental animals, are respiratory. Respiratory stimulation occurs via the vagus. There is an increase in the respiratory minute volume without necessarily an increase in rate, leading to a decrease in the  $p\text{CO}_2$ . Thus a respiratory alkalosis (increase in blood serum pH) leads to cerebral vasodilatation with symptoms of apathy, confusion, coma and an increase in cerebrospinal fluid pressure. Renal compensation follows, producing an increase in bicarbonate in the urine, a decrease in urine chloride, with corresponding rise in plasma chloride and a decrease in serum base. Renal compensation thus leads to loss of base from the body, predominantly as a result of the increased sodium excretion in the urine. In addition, salicylates appear to disturb the metabolism of carbohydrate. An unusually striking and persistent ketosis is associated with or soon follows early symptoms of toxicity. The ketoacidosis produces further base depletion via the kidney, and a true metabolic acidosis may be superimposed upon the respiratory alkalosis. Thus diagnosis of the electrolyte disorder cannot be made merely by determination of the carbon dioxide content of the blood. Measurement of the pH of the blood is of great value when correlated with other findings. Salicylates have an inhibiting effect on the formation of prothrombin by the liver, leading to purpuric manifestations. Dehydration in uncomplicated salicylate poisoning in a well child is usually not striking; however, salicylate poisoning often occurs in children who are ill, and the dehydration produced may be moderate to severe. Vertigo, tinnitus, deafness, visual blurring, anorexia, vomiting, sweating, pallor or flushing, cyanosis, tetany, numbness and tingling of the face, lips and extremities, and bleeding from any area of the body may occur. Laboratory findings of value are acetoneuria and a falsely positive test for diacetic acid with ferric chloride. Diacetic acid produces a burgundy color with ferric chloride, whereas salicylates in the urine produce a violet to a deep purple color. Boiling of acidified urine will volatilize the diacetic acid, producing a negative ferric chloride test in the absence of salicylate. Late evidences of toxicity may

consist of erythematous, scarlatiniform, pruritic, eczematous or desquamative skin lesions.

**Treatment.** See page 196.

68. **Santonin.** The high solubility of santonin in a bile and alkaline solution causes rapid absorption from the upper intestine and leads to rapid development of toxic symptoms. An unknown product is formed which, when excreted, is an aid in diagnosis, since it produces a yellow color in acid urine and a pink color in alkaline urine. Toxic symptoms are manifest initially by a transitory blue vision and later by yellow vision. Other symptoms include headache, vomiting and confusion; with large doses there may be abdominal pain, diarrhea and bloody urine. The skin is cold and clammy and covered with perspiration. A fall in body temperature, a skin rash, tremors, cardiac and respiratory depression and convulsions develop.

**Treatment.** Immediate lavage should be followed by saline catharsis. Intramuscularly administered barbiturates may be used for convulsions.

69. **Shellfish.** Most shellfish poisoning in the United States is due to contamination by staphylococci or to allergic sensitivity. In some localities during certain seasons (summer and fall) mussels and clams may contain powerful neurotoxins. The origin of the poison is thought to be a dinoflagellate in the bodies of the clams. The poison is not destroyed by heating. Three general types of involvement occur: (1) gastroenteritis with nausea, vomiting and diarrhea; (2) nervous symptoms, diffuse erythema, urticaria, angina and dyspnea; and (3) a paralytic form in which symptoms simulate those of curare poisoning with respiratory paralysis.

70. **Sodium Hypochlorite.** Bleaching solutions contain sodium hypochlorite, 3 to 6 per cent in water. Their action is similar to that of sodium hydroxide in high concentrations. Acid secretions in the stomach release irritating hypochlorous acid. Fifteen to 30 ml. orally may be fatal for children. Inhalation of hypochlorous acid fumes produces pulmonary irritation, coughing and choking, and pulmonary edema. Ingestion causes irritation and corrosion of mucous membranes. Edema of the pharynx and larynx may be intense.

**Treatment.** Lavage with sodium bicarbonate solution repeatedly. Administration of a saline cathartic is advisable. Acid antidotes should never be used.

71. **Solanine (Solanism).** Symptoms of poisoning may follow ingestion of sprouted potatoes containing an alkaloid solanine, found in or near the peel. Species of *Solanum* (black night shade, bittersweet) also contain the poison. Vomiting, diarrhea, colicky pains, headaches, depression, pain in the rectum, suppression of urine, and collapse occur within a few hours. Hallucinations and coma are sometimes present.

72. **Strychnine.** Strychnine is a powerful central nervous system stimulant. It produces little local gastrointestinal reaction, and the first symptoms are those of nervous system stimulation. At first a stiffness of the face and neck muscles occurs, followed by hyperactive reflexes of all muscles, and later by muscular twitchings and spinal convulsions. A characteristic position of the body occurs due to the action of the stronger groups of muscles. The back is arched in a position of opisthotonos; the legs are adducted and extended, and the feet turned in; the

fists are clenched and the facial muscles are tightly contracted, producing risus sardonicus; and there is exophthalmos and mydriasis. Involvement of the muscles of respiration produces respiratory arrest with resultant cyanosis. The patient usually remains conscious and is in severe pain. After such a convulsion, which lasts a minute or more, there is a period of relaxation with depression and, in some instances, unconsciousness due to apnea and anoxemia. In ten to fifteen minutes another spinal convulsion occurs. Medullary paralysis, due to excessive stimulation or anoxemia, follows the second to fifth convulsion.

**Treatment.** Lavage should not be done during convulsive attacks. Recurrence of convulsions must be prevented. Large doses of short-acting barbiturates should be given intravenously and repeated if necessary; sodium phenobarbital and amytal are effective. The dose should be sufficient to prevent or stop convulsions and keep the patient asleep, but not to depress respiration or blood pressure. Anesthesia may be temporarily necessary until a barbiturate can be given. All types of stimuli should be avoided. Lavage with 2 per cent tannic acid or strong tea may be performed when the patient is asleep.

73. **Thallium.** Thallium acetate has been administered orally to produce depilation in the treatment of ringworm of the scalp and locally as a depilatory for cosmetic purposes, but owing to the danger of serious toxic effects such use is to be condemned. The initial acute gastrointestinal symptoms, which usually result from accidental ingestion, occur twelve to twenty-four hours after ingestion. There is severe, paroxysmal abdominal pain with vomiting and diarrhea. Hemorrhage, desquamation of the mucosa, and eosinophilia may be present. The late effects of acute or chronic poisoning are predominantly on the nervous system. Peripheral neuritis with paralysis, optic atrophy and cerebral symptoms occur. Alopecia, attributed to a toxic effect on the sympathetic nervous system, is common.

**Treatment.** Essentially the same as for arsenic (9), but BAL is of limited value.

74. **Thiocyanate Insecticides.** These agents induce coma, cyanosis, dyspnea and tonic convulsions. Respiratory difficulty may occur.

**Treatment.** Skin contamination should be removed by scrubbing with soap and water. Gastric lavage with tap water and saline catharsis are advisable. Renal and hepatic injury may occur later.

75. **Veratrine.** An alkaloid obtained from *V. cecadilla* (Sabadilla), a false hellebore plant. Cevadine is crystallized veratrine. Sabadilla dusts and spray and extracts of Sabadilla are used as insecticides and pediculicides. Ingestion produces violent vomiting and diarrhea, intense burning and generalized muscular weakness. Muscular and autonomic nervous system reactions are similar to those from pyrethrum and nicotine.

**Treatment.** See No. 56.

76. **Veratrum.** *Veratrum* and *Zygadenus* are found in Hellebore (*Veratrum album*, *viride* or *californicum*). *Zygadenus venenosus*, the death camass, contains similar nitrogenous compounds. Ingestion of these plants produces nausea, severe vomiting, diarrhea, muscular weakness, visual disturbances, bradycardia and low blood pressure. Very large doses may produce hypertension.

**Treatment.** Gastric lavage followed by saline catharsis. Atropine is of value to block the reflex fall of blood pressure and the bradycardia.

77. **Warfarin (Dicoumarin)** (3- $\alpha$ -acetylbenzyl-4-hydroxycoumarin). A rodenticide found in Dethmor, Rax Powder, D-con and other products. Available in 1:200 concentration in cornstarch and used as a rat bait in 1:400 concentration in corn meal. The dicoumarol action inhibits prothrombin formation, but it is forty times more potent than dicoumarol. Absorption is slow and irregular; twenty-four to forty-eight hours may elapse before any effect is noted. Elimination is slow. The action is chiefly on the synthesis of prothrombin with a gradual depression of prothrombin levels in the blood leading to spontaneous hemorrhages. The action may persist for ten days.

**Treatment.** Gastric lavage and catharsis should be instituted. Vitamin K in large doses should be given intravenously. Whole blood transfusions may also be needed.

78. **Zinc Stearate Powder.** A severe irritation of the respiratory mucous membranes is produced by aspiration with resulting congestion, hyperemia, edema, and obstruction of bronchioles with mucus. Bronchopneumonia is common in infants who survive the first day or two. Choking, coughing, cyanosis and signs of suffocation tend to develop immediately.

**Treatment.** Aspiration of the powder and accumulated secretions by bronchoscopy is worthy of trial, but it is not likely to be effective because of the adhesive quality of the powder. Administration of oxygen is important, and there may be an added advantage in giving it in combination with helium. Powders containing zinc stearate should *never* be used for infants and small children.

### LIST OF CHEMICALS

The following list includes individual chemical compounds, alphabetically arranged, with an appended numeral referring to the class (see p. 1383) with which they are associated; e.g., Chloroethane (46) is referred to Hydrocarbons (Halogenated).

Abrin, 1  
Acetaldehyde (ethyl aldehyde), 39  
Acetanilid (N-phenylacetamide), 6  
Acetic acid, concentrated, 2  
Acetoarsenite (Paris green), 9  
Acetone, 3  
Acetophenetidin (phenacetin), 6  
Acetylene tetrachloride (tetrachloroethane), 46  
Acetyl salicylic acid (Aspirin), 67  
Acid. See particular acid.  
Acid-like substances, 2  
Aconite (aconitine), 53  
Alcohol, 3  
Alcohol, ethyl (ethanol, grain alcohol, neutral spirits), 3  
Aldehydes, 39  
Aldrin (Compound 118), 25  
Alkalis, corrosive, 49  
Allethrin (Allyn cinerin), 56  
Allyl-isopropylacetyl-carbamide (Sedormid), 13

Allyn cinerin (Allethrin), 56  
Aluminum salts, 4  
Amanita, 55  
p-Aminophenol, 6  
Aminopyrine (Amidopyrine), 6  
Ammonia (ammonium hydroxide), 49  
Ammoniated mercury, 51  
Ammonium hydroxide (ammonia), 49  
Amobarbital (Amytal), 13  
Amphetamine, 5  
Amyl nitrite, 57  
Amytal (Amobarbital), 13  
Andromedotoxin, 54  
Aniline (phenylamine), 6  
Antihistaminics, 13  
Antimony, 7  
Antipyrene, 6  
ANTU, 8  
Arochlor, 46  
Arsenates and arsenites, 9  
Arsenic trioxide (white arsenic), 9  
Aspidium, 10  
Aspirin (acetyl salicylic acid), 67  
Asterol, 11  
Atropine, 12  
Barbital (Veronal), 13  
Barbiturates, 13  
Barium salts, 14  
Benadryl, 13  
Benzalkonium chloride (Zephiran), 35  
Benzene (Benzol), 15  
Benzene hexachloride (hexachlorocyclohexane), 25  
Benzethonium chloride (Phemorol), 35  
Benzine, 45  
Benzol (Benzene), 15  
Beta-naphthol ( $\beta$  naphthol), 62  
Bichloride of mercury (mercuric chloride, corrosive sublimate), 51  
Bismuth, 16  
Bismuth subnitrate, 57  
Boracic acid (boric acid), 17  
Borate salts, 17  
Borax (sodium tetraborate), 17  
Boric acid (boracic acid), 17  
Boron, 17  
Bromate, methyl, 46  
Bromate salts, 18  
Bromides, 19  
Brown Mixture (contains tartar emetic), 7  
Butcaine, 28  
Cadmium salts, 20  
Calcium hypochlorite (chlorinated lime), 70  
Calomel (mercurous chloride), 51  
Campho-phenique, 62  
Camphor (gum camphor), 62  
Camphor tar (naphthalene, naphthene), 15  
Carbitol, 3  
Carbolic acid (phenol, hydroxybenzene), 62  
Carbon bisulfide (carbon disulfide), 21  
Carbon monoxide, 22  
Carbon tetrachloride (perchloromethane), 46  
Castrix, 72  
Catechol (Pyrocatechol), 62  
Caustic potash (potassium hydroxide), 49  
Caustic soda (sodium hydroxide), 49  
Ceepryn chloride (cetyl pyridinium chloride), 35  
Cetyl pyridinium chloride (Ceepryn chloride), 35  
Chenopodium oil (wormseed oil), 23

- Chloral hydrate, 13  
Chlordane (Compound 1068), 25  
Chloride, methyl, 46  
Chlorinated camphene (Toxaphene, Compound 3956, octachlorocamphene), 25  
Chlorinated diphenyl, 46  
Chlorinated insecticides, 25  
Chlorinated lime (calcium hypochlorite), 70  
Chlorinated naphthalene, 46  
Chlorine water, 49  
Chloroacetic acid, 43  
Chloroaniline, 6  
Chlorobenzene, 24  
Chlorobutanol, 13  
Chloroethane (ethyl chloride), 46  
Chloroform (trichloromethane), 46  
Chlorohydrin, ethylene, 46  
Chloronitrobenzene, 6  
Chromate salts, 26  
Chromic acid, 2  
Cicutoxin, 72  
Cleaning solutions, 27  
Clorox, 70  
Cobalt salts, 2  
Cocaine, 28  
Codeine, 60  
Colchicum autumnale, 50  
Compound 42 (Warfarin), 77  
Compound 118 (Aldrin), 25  
Compound 1068 (Chlordane), 25  
Compound 1080 (sodium fluoroacetate), 43  
Compound 1836 (diethyl 2-chloro-vinyl phosphate), 65  
Compound 3956 (Toxaphene, chlorinated camphene, octachlorocamphene), 25  
Coniine, 29  
Copper acetoarsenite (Paris green), 9  
Copper arsenate, 9  
Copper salts, 2  
Corrosive acids, 2  
Corrosive alkalis, 49  
Corrosive sublimate (mercuric chloride, bichloride of mercury), 51  
Cosmetics, 30  
Cough medicines, 31

## ACRODYNIA

(PINK DISEASE, SWIFT'S DISEASE, FEER'S DISEASE, ERYTHREDEMA, DERMATO-POLYNEURITIS)

Acrodynia (the term, derived from the Greek, denotes painful extremities) is a syndrome consisting of many unusual symptoms which form a characteristic clinical pattern. A relatively large number (at least eleven) of etiologic possibilities have been suggested, but only one has substantial support. Warkany and Hubbard assembled convincing data that most, if not all, instances of acrodynia are the result of an unusual sensitivity or idiosyncrasy to mercury.

The diagnosis is based on the clinical appearance and the course of the disease, which in the well established case are so distinctive that there is practically no differential diagnosis. The characteristic clinical manifestations which make up this unusual syndrome are extreme irritability and restlessness alternating with periods of apathy; insomnia; anorexia; profuse perspiration; pink hands and feet and scarlet tip of nose and cheeks; inconstant and variable generalized skin rashes; desquamation; itching, which causes the child to rub the body and especially the extremities against the bed or other objects, initiating trophic ulcers; photophobia; alopecia; salivation; loss of teeth and nails and, rarely, of phalanges; pain in the extremities; hypotonia; rapid pulse rate; and increased blood pressure. The great discomfort causes the child to be extremely restless, and the hypotonia permits him to assume many different and bizarre positions. There are few clinical conditions

in which extreme and persistent misery is such a prominent part of the clinical picture.

**History.** As early as 1903 Selter of Solingen, in an address which attracted little attention, described this disease and called it a trophodermatosis. Feer of Zurich, whose name is attached to the disease in Europe, did not know that such a clinical entity existed until the early 1920's, when he described his interpretation of it as "Vegetative Neurose des Kleinkindes." The condition had been recognized in Australia as early as 1890 as "pink disease"; but it was not until 1914 that Swift's paper brought it into focus as a distinct clinical entity under the name "erythredema." His article was published in the transactions of an Australian society which were not widely distributed. The disease had been observed and commented upon as early as 1915 in Oregon, but there was nothing in British or American literature on the condition until two physicians in the United States independently published articles describing it in 1920.

**Etiology.** Acrodynia is principally a disease of infancy and early childhood. In the United States it has become uncommon except in the southeastern states, where the incidence is apparently also decreasing. The highest incidence seems to be in Australia, with relatively large numbers of cases observed in France, Switzerland and England.

Acrodynia has been ascribed to avitaminosis, chronic infections, a combination of dietary deficiency and infection, poisoning with a variety of substances, including the fungus of maize and rye, and a number of different chemicals, especially arsenic and mercury, and to unspecified viral agents. Feer, impressed with such clinical manifestations as hypertension, tachycardia and excessive sweating, concluded that the syndrome resulted from an overactivity of the sympathetic nervous system.

On the basis of the similarity of some of the clinical manifestations of acrodynia to poisoning with mercury or arsenic, Warkany and Hubbard (1945) made a systematic search for heavy metals in the urine of an infant with acrodynia. The only one detected was mercury. Since this observation, mercury has been demonstrated in the urine of a large number of infants with the syndrome; Warkany and Hubbard in twenty-five of twenty-eight patients, Fanconi and Botsztein in Switzerland in nineteen of twenty, and Holzel and James in England in sixty-one of ninety-four. Mercury has been demonstrated in the urine of persons ingesting it who had no manifestations of acrodynia. Such observations, however, are uncommon, and in general the amounts demonstrated in the urine

of patients with acrodynia have been considerably greater than in that of apparently healthy persons.

The incidence of mercury in urine would seem to be highest in geographic areas where mercurial medications are or have recently been widely prescribed. In the southern United States and in England, where mercurial teething powders and lotions have been used extensively, the peak incidence is under one year of age, whereas in France and Switzerland, where mercurial vermifuges are more widely used, the peak incidence is between two and four years of age. Other reported sources of mercury include calomel, mercurial ointments, diaper rinses and protiodide of mercury in the form of pills. The possibility of accidental ingestion, of course, exists.

If mercury, or less frequently other chemicals such as arsenic, gold and thallium, should be the etiologic agent or agents of acrodynia, the question must be answered: Why do only relatively few of the persons who come in contact with them acquire the disease? At present there is no better answer than that the clinical pattern represents an unusual sensitivity or idiosyncrasy to heavy metal. It should be recognized, however, that mercury is not universally accepted as the etiologic factor in acrodynia.

**Pathology.** No consistent or characteristic pathologic changes have been observed. Many of the observations can be explained on the basis of a chronic disease in association with a state of semistarvation with resultant degeneration of nervous tissue. A patient of the author's with extremely severe symptoms of acrodynia was thoroughly studied by means of many sections of the entire nervous system (brain, cord, peripheral nerves and the sympathetic ganglia and their nerves). No information was obtained which could contribute to an understanding of the disease.

**Clinical Manifestations.** There are all grades of severity. The child becomes listless; he is no longer interested in play and is restless and irritable. There may be an associated upper respiratory tract infection. Generalized, inconstant rashes which are protean recur from time to time. Early the tips of the fingers and toes acquire a pinkish color, and later the hands and feet become a dusky pink which shades off at the wrists and ankles; they are cold and clammy. These changes in the extremities are the most distinctive features of the syndrome, being different from those of any other disease occurring in children, and

are responsible for the term "pink disease." Frequently the cheeks and the tip of the nose acquire a scarlet color.

As the disease becomes established, the sweat glands are enormously dilated and enlarged, causing perspiration to become profuse; at times the infant may actually be drenched, necessitating frequent changes of clothing. A severe pyoderma may develop. There is desquamation of the soles and palms, which, though usually superficial, may be marked and may disappear and recur during the course of the disease. The fingers and toes appear edematous; the swelling is due to hyperplasia and hyperkeratosis of the skin. Fever is usually not present unless there is some complication as pyuria or bronchopneumonia. An outstanding symptom is excruciating pain in the hands and feet. Children will rub their hands together for hours, and older children will complain of a severe burning sensation. In more than 60 per cent of the cases there is a photophobia without evidence of local inflammation of the eyes. The children shield their eyes or bury their faces in their pillows. The lax ligaments and hypotonia permit the children to assume unusual positions (Fig. 427), and they often lie for hours with their heads between their legs. The so-called salaam position is frequently assumed, often with constant rubbing motions of the hands and feet, owing to the pain and itching.

One of the most dramatic occurrences is the loss of a nondecayed tooth. In extreme cases all the teeth may be lost; necrosis of the jaw bones frequently follows. Initially the gums appear normal except for a slightly deeper red color; later they become markedly inflamed and swollen. Salivation then becomes pronounced, and the saliva often flows from the mouth in a constant stream. The nails become darker and frequently drop off. Occasionally gangrene of the toes and fingers develops, and trophic ulcers may result from the constant rubbing of the hands and feet. The hair tends to fall out and is often pulled out by the child. Anorexia is marked, but because of the excessive perspiration large quantities of water are consumed. There may be diarrhea, and prolapse of the rectum is a frequent complication. The blood pressure and pulse rate even in infants may be increased.

The nervous symptoms are an important part of the syndrome. Whether they are due to specific lesions cannot be stated. Early in the disease the tendon reflexes may be normal

FIG. 427. Extreme hypotonia and photophobia in an infant with acrodynia. This bizarre position may be maintained for hours.

or increased, but later they disappear. There is not a true motor paralysis, but because of the soft, flabby musculature the child has no desire to walk. Many of the symptoms and signs suggest involvement of the vasomotor mechanism. The severe pain prevents normal sleep. There is no time when a child with acrodynia appears happy or comfortable; he does not play or smile, but appears dejected and melancholic, a picture of abject misery.

**Laboratory Data.** There are no characteristic morphologic changes of the blood or significant changes in the cerebrospinal fluid. There may be albuminuria, but there are no characteristic urinary findings other than the presence of mercury.

**Prophylaxis.** There is little need for mercurial medications in pediatric practice, and they should be avoided whenever possible. Perhaps it is most important at the moment to be alert for possible contacts with mercury in various household and industrial preparations.

**Treatment.** In 1948 Bivings and Lewis treated acrodynia in an infant whose urine contained mercury, with BAL (British anti-lewisite; 2, 3-dimercaptopropanol) with apparently good effect. In general, subsequent results have been favorable, especially when administration was begun early in the disease. The recommended plan of treatment is 3 mg. per kilogram of body weight of BAL every four hours for forty-eight hours, then every six hours for twenty-four hours, followed by administration at intervals of twelve hours for seven days. The drug is administered intramuscularly in a 10 per cent solution. Toxic effects of BAL have been observed (p. 1381).

The natural course of acrodynia is prolonged, extending from several months to a

year. There is probably no more difficult therapeutic problem in pediatrics than the management of an infant with severe acrodynia. The extreme restlessness, irritability and pain are not readily allayed. In view of the long duration of the disease opiates should not be given, except for temporary emergencies, to avoid the danger of habit formation. Barbiturates are usually not as effective as paraldehyde administered rectally in olive oil (5 to 10 cc.). Symptomatic relief has also been reported from the use of Priscoline in doses of 12.5 mg. at intervals of four to six hours.

The diet should contain generous amounts of proteins, minerals and vitamins. Frequently anorexia is so great that feeding must be by gavage.

Owing to the profuse sweating, thirsting is usually prominent, and, in contrast to the frequent refusal to eat, the child will usually take relatively large quantities of fluids. Any deficits of sodium, chloride or potassium should be taken into account in the planning of emergency parenteral fluid therapy. So far as possible fluid intake should be oral rather than parenteral. If milk is not taken well, it can be supplemented with fruit juices, glucose in Ringer's solution, and water.

The child should be kept as clean as possible to minimize the chances of secondary pyogenic skin infections. Frequent alcohol rubs may aid in this respect in addition to being soothing for the child. The clothing should be light, preferably of cotton, and should be changed frequently when perspiration is profuse.

Mortality rates have been significantly higher in hospitalized patients than in those treated at home because of their susceptibility

to cross infections. It is obvious that the family must be made aware of the nature of the illness and of its prolonged course if they are to be expected to play their part successfully.

Potassium . . . . . (serum)	133-143	mEq./liter
Calcium . . . . . (serum)	307-330	mg./100 ml.
Calcium, diffusible (ionized Ca) . . . . . (serum)	4.1-5.6	mEq./liter
Magnesium . . . . . (serum)	16-22	mg./100 ml.
Chlorides, expressed as Cl . . . . . (serum)	5-6	mEq./liter
At birth and during early infancy the plasma (serum) chloride is 6-10 mEq./liter higher than that of older infants and children	10-12	mg./100 ml.
expressed as NaCl . . . . . (serum)	5-5.5	mg./100 ml.
The chloride concentration of whole blood depends largely on the cell volume, since the cells contain approximately half as much chloride as serum	1.65-2.5	mEq./liter
Phosphorus, inorganic, as P . . . . . (serum)	2-3	mg./100 ml.
HPO <sub>4</sub> <sup>-</sup> , H <sub>2</sub> PO <sub>4</sub> <sup>-</sup> (average valence 1.8 at pH 7.4). Slightly higher in newborn infants, then decreasing during childhood	100-106	mEq. liter
Sulfates, inorganic, as SO <sub>4</sub> <sup>-</sup> . . . . . (serum)	355-376	mg./100 ml.
Sulfates, ethereal . . . . . (serum)	100-106	mEq./liter
Sulfur, neutral . . . . . (serum)	585-620	mg./100 ml.
Lactic acid . . . . . (serum)	1.45-1.77	mM./liter
Serum protein-base binding power . . . . . (serum)	4.5-5.5	mg./100 ml.
Bicarbonate bound base . . . . . (serum)	2.6-3.2	mEq. liter
pH at 38° C . . . . . (blood, plasma or serum)	0.5-1.0	mEq./liter
Arterial blood in a resting person is about 0.03 pH unit higher than venous blood	2.5-5.0	mg./100 ml.
pH at 38° C . . . . . (serum from arterial blood)	0.1-1.0	mg./100 ml.
(Data from Cassels and Morse)	1.7-3.5	mg./100 ml.
1-5-3.4 years . . . . .	10-20	mg./100 ml.
3.5-5.4 years . . . . .	1.1-2.2	mEq./liter
5.5-12.4 years . . . . .	15.5-18.0	mEq. liter
12.5-17.4 years . . . . .	19-30	mEq. liter
	7.3-7.45	
	7.35-7.41	

Table 119 (Continued)

Water.....	(whole blood)	79-81	gm./100 ml.
	(serum)	91-92	gm./100 ml.
	(red blood cells)	64-65	gm./100 ml.
Carbon dioxide content.....	(serum from venous blood)	45-70	vol. per cent
		20.3-31.5	mM./liter
The CO <sub>2</sub> content is lower at birth and rises slightly during the first four days of life			
Carbon dioxide content.....	(whole venous blood)	40-60	vol. per cent
		18.0-27.0	mM./liter
Carbon dioxide content.....	(arterial blood)		
(Data from Cassels and Morse)			
1.5- 3.4 years.....		34.5-45.7	vol. per cent
Carbon dioxide content			
3.5- 6.4 years.....		41.7-47.1	vol. per cent
6.5-11.4 years.....		43.0-48.0	vol. per cent
11.5-14.4 years.....		44.3-49.4	vol. per cent
14.7-17.4 years.....		45.4-49.6	vol. per cent
Carbon dioxide tension.....	(arterial blood)		
(Data from Cassels and Morse)			
1.5- 6.4 years.....		33.5-41.1	mm. Hg
6.5-12.4 years.....		35.4-40.6	mm. Hg
12.5-17.4 years.....		38.3-44.4	mm. Hg
Oxygen capacity*.....	(whole blood)	19-22	vol. per cent
Oxygen saturation.....	(whole venous blood)	60-85 per cent	
Hemoglobin*			
At birth.....	(whole blood)	17-20	gm./100 ml.
3 months.....	(whole blood)	10.5-12	gm./100 ml.
1 year.....	(whole blood)	11-12.5	gm./100 ml.
5 years.....	(whole blood)	12-13	gm./100 ml.
10 years.....	(whole blood)	13-14	gm./100 ml.
Above 10 years.....	(whole blood)	14-16	gm./100 ml.
Methemoglobin.....	(whole blood)	0.0-0.3	gm./100 ml.
Premature infants at higher level.....		(0.4)	

*Carbohydrates, Lipids and Pigments*

Sugar, fasting arterial blood.....		80-120	mg./100 ml.
fasting venous blood.....		70-100	mg./100 ml.
fasting venous blood (Folin-Wu procedure).....		85-120	mg./100 ml.
Pyruvic acid, fasting whole blood.....		0.7-1.2	mg./100 ml.
Total lipids (fats).....	(serum)	500-700	mg./100 ml.
Total cholesterol.....	(serum)	170-250	mg./100 ml.
Total cholesterol, infant.....		80-125	mg./100 ml.
At birth serum cholesterol averages 75 mg./100 ml.			
Cholesterol esters.....	(serum)	125-180	mg./100 ml.
Bilirubin.....	(serum)	0.2-0.8	mg./100 ml.
Higher in newborn infants.....		1 or more	mg./100 ml.
Icterus index.....	(serum)	4-6	

*Proteins†*

Total protein.....	(serum)	6.5-7.5	gm./100 ml.
At birth the protein level is slightly lower			
Albumin (fractionation by Na <sub>2</sub> SO <sub>4</sub> [22 per cent] precipitation of globulin).....	(serum)	4.5-5.5	gm./100 ml.

\* The oxygen capacity and iron content of blood are directly related to the hemoglobin content of blood.

† The total protein as determined from electrophoretic measurements is slightly lower than the values above (6.0-6.7). By electrophoretic fractionation the albumin is about 55 per cent of the total protein; alpha 1 globulin, 5 per cent; alpha 2 globulin, 9 per cent; beta globulin, 13 per cent; gamma globulin, 11 per cent; fibrinogen, 7 per cent.

When globulins are precipitated with 26.8% Na<sub>2</sub>SO<sub>4</sub> or with a mixture containing 20.8% Na<sub>2</sub>SO<sub>4</sub> and 7.0% Na<sub>2</sub>SO<sub>3</sub>, albumin values are obtained which match those obtained by electrophoretic measurements.

Table 119 (Continued)

Globulin (by difference).....(serum)	1.7-3.0	gm./100 ml.
Protein values vary slightly with age. The following values for plasma are adapted from the paper of Metcalf and Stare (New England J. Med., 1947)		
Total protein (plasma)		
Premature infant.....	4.55 $\pm$ 0.59	gm./100 ml.
Full term infant.....	5.11-5.70	gm./100 ml.
Birth to 1 year.....	6.10 $\pm$ 0.29	gm./100 ml.
1-4 years.....	6.94 $\pm$ 0.47	gm./100 ml.
5-12 years.....	7.30 $\pm$ 0.59	gm./100 ml.
12 years and above.....	7.16	gm./100 ml.
Albumin (plasma)		
Premature infant.....	3.55 $\pm$ 0.65	gm./100 ml.
Full term infant.....	3.76-3.79	gm./100 ml.
Birth to 1 year.....	4.97 $\pm$ 0.73	gm./100 ml.
1-4 years.....	4.59-4.83	gm./100 ml.
5-12 years.....	5.0 $\pm$ 0.78	gm./100 ml.
12-15 years.....	4.72	gm./100 ml.
Globulin (plasma)		
Premature infant.....	1.01 $\pm$ 0.45	gm./100 ml.
Full term infant.....	1.34-1.66	gm./100 ml.
Birth to 1 year.....	1.38 $\pm$ 0.68	gm./100 ml.
1-4 years.....	2.03 $\pm$ 0.34	gm./100 ml.
5-12 years.....	2.4 $\pm$ 0.74	gm./100 ml.
12-15 years.....	2.49	gm./100 ml.
Fibrinogen (plasma).....	0.2-0.4	gm./100 ml.
Gamma globulin.....	10-15	% of total protein
	0.7-1.2	gm./100 ml.

At birth values approximate adult levels, owing to passive transfer from the mother; during the ensuing weeks there is a decrease, the "low point" being reached between the second and fourth months. After this there is a gradual increase to the "adult level" by about the second year of life.

## Nitrogen Constituents

Nonprotein nitrogen.....(whole blood)	25-40	mg./100 ml.
Urea nitrogen.....(plasma)	18-30	mg./100 ml.
.....(whole blood)	7-15	mg./100 ml.
Creatine + creatinine.....(plasma)	10-17	mg./100 ml.
.....(whole blood)	5-8	mg./100 ml.
Creatine in low concentration in plasma		
Creatinine.....(whole blood)	0.5-2	mg./100 ml.
.....(plasma)	0.6-1.2	mg./100 ml.
Uric acid.....(whole blood)	2.5-3.5	mg./100 ml.
At birth the uric acid concentration of the infant's blood is identical with that of the mother		
Ammonia.....(whole blood)	0.1-0.3	mg./100 ml.
Amino acid nitrogen.....(plasma)	3.5-5.5	mg./100 ml.
Plasma rather than serum is recommended for the amino acid nitrogen, since serum gives slightly lower values		

## Miscellaneous

Phosphatase, infants.....(serum)	5-10	Bodansky units
children 2-15 years.....	3-13	Bodansky units
infants.....(serum)	0.5-1.14	Kay units
children.....	0.17-0.34	Kay units
infants.....(serum)	156-241	Lundsteen and
children.....	43-147	Vermehren units
children.....(serum)	3.4-11.0	Lundsteen and
children.....(serum)	15-20	Vermehren units
children.....(serum)	35-40	Jenner-Kay units
		King-Armstrong units
		Cayla units

Table 119 (Continued)

Amylase.....	(plasma)	80-150	Somogyi units
Ascorbic acid.....	(serum)	0.4-1.5	mg./100 ml.
Iron (above 10 years).....	(whole blood)	47-55	mg./100 ml.
See note under Oxygen Capacity			
Iron.....	(serum)	0.04-0.18	mg./100 ml.
Copper.....	(serum)	0.08-0.13	mg./100 ml.
Lead.....	(serum)	0.001-0.003	mg./100 ml.
Iodine, organic (protein-bound).....	(serum)	0.003-0.008	mg./100 ml.
Plasma volume (Metcoff and Stare), Evans blue method			
Neonatal.....		144-164	ml.
Under 1 year.....		144-270	ml.
1-4 years.....		483-653	ml.
5-12 years.....		891-1590	ml.
13-16 years.....		2030-2610	ml.
Physical Measurements			
<hr/>			
Specific gravity.....	(whole blood)	1.048-1.050	
Newborn infants: falls rapidly during first two weeks and continues to decrease until second or third year	(whole blood)	1.060-1.085	
	(plasma)	1.025-1.030	
Prothrombin time (Quick).....	(plasma)	12-15	seconds
This determination should always be controlled by a determination on a normal blood, since the activity of the thromboplastin preparations may vary markedly			
Bleeding time.....		1-3	minutes
Coagulation time (test tube method).....		3-9	minutes
Viscosity, compared to water as unity.....	(whole blood)	4.5-5.5	
	(serum)	1.7-2.1	
Corrected sedimentation rate (Rourke-Ernstene).....		0.1-0.35	mm./min.
Cutler method.....		2-10	mm./hr.
The rate is slower in the neonatal period			
Freezing point depression.....	(serum)	-0.535°-(-0.555°) C.	
Refractive index, 20° C.....		1.3485-1.3505	

NORMAL CEREBROSPINAL FLUID VALUES

Amount in the newborn.....		up to 5 ml.
Increases with age to adult figure.....	100-150	ml.
Initial pressure.....	70-200	mm. of water
Cell count		
Under 1 year.....		up to 10 cells/c. mm.
1-4 years.....		up to 8 cells/c. mm.
5 years to puberty.....		0-5 cells/c. mm.
Specific gravity.....		1.005-1.009
Viscosity.....		1.0424-1.0489
Freezing point depression.....		-0.56-(-0.60)° C.
Refractive index at 20° C.....		1.33554
pH 38° C. (protected against loss of CO <sub>2</sub> ).....	7.33-7.42	
Fluid exposed to air becomes alkaline		
Carbon dioxide-combining power.....	40-70	vol. per cent
Chloride, as NaCl		
7 days-3 months.....	636-716	mg./100 ml.
	108.8-122.5	mEq./liter
	659-742	mg./100 ml.
4-12 months.....	112.7-128.5	mEq. liter
	683-763	mg./100 ml.
13 months-12 years.....	116.8-130.5	mEq./liter

Cholesterol	trace-0.22	mg./100 ml.
Glucose, 6 months-10 years	71-90	mg./100 ml.
over 10 years	50-80	mg./100 ml.
Total base	about 155	mEq. liter
Sodium	300-380	mg./100 ml.
Potassium	11-16	mg./100 ml.
Calcium	4.5-5.5	mg./100 ml.
Magnesium	2.8-3.3	mg./100 ml.
Phosphorus, inorganic	1.0-2.0	mg./100 ml.
3 mg. first day of life		
Lactic acid		Trace
Fluid on standing may increase in concentration with disappearance of glucose		
Protein	15-40	mg./100 ml.
The ventricular fluid contains much less protein than does lumbar fluid		
Fluid from the cisterna magna contains more protein than that from the ventricle and less than that from lumbar region		
Albumin		80% of total protein
Globulin		20% of total protein
Fibrinogen		none
Pandy reaction		no precipitate
Urea nitrogen	7-15	mg./100 ml.
Nonprotein nitrogen	8.5-20	mg./100 ml.
Creatinine	0.45-1.90	mg./100 ml.
Uric acid	0.3-1.5	mg./100 ml.
Amino acid nitrogen	1.5-3	mg./100 ml.
Bilirubin		none
Iodine		trace
Colloidal gold number (Wuth and Faupel)		0000000000
Dilutions 1:10 to 1:5120 with 0.4% NaCl solution.		

METHOD FOR CONVERSION OF  
MILLIGRAMS TO MILIEQUIVALENTS PER LITER

mg. = milligrams                      ml. = milliliter  
gm. = grams                          1 ml. = 1.000027 cc.  
mEq./liter (milliequivalents per liter) =  $\frac{\text{mg. per liter}}{\text{equivalent weight}}$

equivalent weight =  $\frac{\text{atomic weight}}{\text{valence of element}}$

For example: A sample of blood serum contains 10 mg. of Ca in 100 ml. The valence of Ca is 2, and the atomic weight is 40. The equivalent weight of Ca is therefore  $40 \div 2$ , or 20. The milliequivalents of Ca per liter is  $10 \times 10 \div 20$ , or 5 milliequivalents per liter.

mM./liter (millimols per liter) =  $\frac{\text{mg./liter}}{\text{molecular weight}}$

vol. % (volumes per cent) = mM./liter  $\times 2.24$  for a gas whose properties approach that of an ideal gas, such as oxygen or nitrogen.

For carbon dioxide the factor is 2.226.

Table 120. Factors for Conversion of Concentrations Expressed in Milliequivalents per Liter to Milligrams per 100 Milliliters, and vice versa, for Common Ions That Occur in Physiologic Solutions

Element or Radical	mEq. per Liter	Mg. per 100 ML.	Mg. per 100 ML.	mEq. per Liter
Sodium	1	2.30	1	0.4348
Potassium	1	3.91	1	0.2558
Calcium	1	2.005	1	0.4988
Magnesium	1	1.215	1	0.8230
Chloride	1	3.55	1	0.2817
Bicarbonate (HCO <sub>3</sub> )	1	6.1	1	0.1639
Phosphorus valence 1	1	3.10	1	0.3226
Phosphorus valence 1.8	1	1.72	1	0.5814
Sulfur valence 2	1	1.60	1	0.625

Example: To convert milliequivalents of magnesium per liter to milligrams per 100 milliliters, multiply by the factor 1.215.

To convert milligrams of potassium per 100 milliliters to milliequivalents per liter, multiply by the factor 0.2558.

Table 121. Milliequivalents and Milligrams of Cations and Anions Present in a Millimol of Salts Commonly Used in Physiologic Solutions

Salt	mM. per Liter	Mg. per Liter	Cation	Anion	mEq. Cation per Liter	Mg. Cation per Liter	mEq. Anion per Liter	Mg. Anion per Liter
Sodium chloride (NaCl)	1	58.5	Na <sup>+</sup>	Cl <sup>-</sup>	1	23.0	1	35.5
Potassium chloride (KCl)	1	74.6	K <sup>+</sup>	Cl <sup>-</sup>	1	39.1	1	35.5
Sodium bicarbonate (NaHCO <sub>3</sub> )	1	84.0	Na <sup>+</sup>	HCO <sub>3</sub> <sup>-</sup>	1	23.0	1	61.0
Sodium lactate (CH <sub>3</sub> CH(OH)COONa)	1	112.0	Na <sup>+</sup>	Lactate <sup>-</sup>	1	23.0	1	89.0
Potassium phosphate (K <sub>2</sub> HPO <sub>4</sub> ) dibasic	1	174.2	K <sup>+</sup>	HPO <sub>4</sub> <sup>-</sup>	2	78.2	1	96.0
Potassium phosphate (KH <sub>2</sub> PO <sub>4</sub> ) monobasic	1	136.1	K <sup>+</sup>	H <sub>2</sub> PO <sub>4</sub> <sup>-</sup>	1	39.1	1	97.0
Calcium chloride anhydrous (CaCl <sub>2</sub> )	1	111.0	Ca <sup>++</sup>	Cl <sup>-</sup>	2	40.0	2	71.0
Calcium chloride dihydrate (CaCl <sub>2</sub> ·2H <sub>2</sub> O)	1	147.0	Ca <sup>++</sup>	Cl <sup>-</sup>	2	40.0	2	71.0
Magnesium chloride anhy- drous (MgCl <sub>2</sub> )	1	95.2	Mg <sup>++</sup>	Cl <sup>-</sup>	2	24.3	2	71.0
Magnesium chloride hexahy- drate (MgCl <sub>2</sub> ·6H <sub>2</sub> O)	1	203.3	Mg <sup>++</sup>	Cl <sup>-</sup>	2	24.3	2	71.0
Ammonium chloride (NH <sub>4</sub> Cl)	1	53.5	NH <sub>4</sub> <sup>+</sup>	Cl <sup>-</sup>	1	18.0	1	35.5

MILLIOSMOLAR SOLUTION: In studying osmotic pressure relationships in solution it is useful to express the concentration in terms of ionic concentrations. The term "milliosmolar" is used instead of millimolar to show the additive osmotic effect of the ions.

For example: A millimolar solution of glucose (180 mg. per liter) is also a milliosmolar solution (1 milliosmol per liter), because there is no increase in the number of active particles through ionization. A millimolar solution of sodium chloride (58.5 mg. per liter) contains one chemical milliequivalent of sodium ions and one chemical milliequivalent of chloride ions. The milliosmolar concentration is 2 milliosmols per liter, because one chemical milliequivalent of sodium or chloride ions is equal to 1 milliosmol of sodium or chloride ions, respectively. This is true for all univalent ions. The chemical milliequivalence of a divalent ion is twice the milliosmolar value. In a millimolar solution of calcium chloride (CaCl<sub>2</sub>) there are two chemical milliequivalents of calcium ions, but only 1 milliosmol of calcium ions. The millimolar solution of calcium chloride contains two chemical milliequivalents of chloride ions or 2 milliosmols of chloride ions per liter. A millimolar solution of calcium chloride contains 3 milliosmols per liter, because it ionizes into one calcium ion and two chloride ions.

In blood serum containing 10 mg. of calcium per 100 ml., there are 5 chemical milliequivalents of calcium per liter, but only 2.5 milliosmols of calcium per liter. The average normal total ionic concentra-

FIG. 428. Nomogram for estimation of serum ionized calcium from total calcium and total protein values. Modified by Lytt I. Gardner from the McLean-Hastings data. (J. Biol. Chem., Vol. 108.)

tion of blood serum is 290 milliosmols; cation concentration 151, anion concentration 139. The osmotic pressure of the blood serum of infants and children is comparable to that of adults.

HOWARD W. ROBINSON

To convert requirements per kilogram of body weight to requirements per pound of body weight, divide the value per kilogram by 2 and subtract 10 per cent of the product.

METHOD FOR DIET CALCULATION\*

The following is a convenient method for calculation of diabetic and other quantitative diets which can be used by the average practitioner. It is sufficiently accurate for clinical use. The principle is based on the classification of foods on the basis of the approximate equality of their carbohydrate, protein and fat contents, so-called food equivalents (see Tables 123 and 124).

The steps for determining the diet for a given child are as follows:

- 1. Determine dietary prescription.  
(For diabetic diet, see p. 1209)  
(For obesity diet, see p. 356)  
Example below based on diabetic diet of C, 200; P, 70; F, 80.
- 2. List number of servings from each list of food exchanges in Table 124, which are considered essential for the basic needs of the child; tabulate

Example:

List	Food	No. of Servings	Carbo- hydrate Gm.	Pro- tein Gm.	Fat Gm.
1.....	Milk	4 cups (1 qt.)	48	32	40
2a....	Vegetables	As desired	0	0	0
2b....	Vegetables	4	28	8	0
3.....	Fruit	3	30	0	0
4.....	Bread	4	60	8	0
5.....	Meat	3	0	21	15
6.....	Fat	4	0	0	20
			166	69	75

amounts of carbohydrate, protein and fat for each list and total each element separately.

3. Subtract amounts of carbohydrate, protein and fat in (2) from amount of each specified for the prescribed diet.

	Carbohydrate Gm.	Protein Gm.	Fat Gm.
Prescribed diet.....	200	70	80
Basic diet.....	166	69	75
Deficit.....	34	1	5

4. Make up deficits of carbohydrate, protein and fat in preliminary diet list (step 2) by adding appropriate number of servings from any of the lists of food exchanges (Table 124), based on child's dietary habits and desires.

Example:

List	Serving	Carbohydrate Gm.	Protein Gm.	Fat Gm.
3.....	3	30	0	0
4.....	1	5	2	0
6.....	1	0	0	5
		35	2	5
Basic Diet.....		166	69	75
Final prescription....		201	71	80

\* Adapted from E. K. Caso and F. J. Stare: Simplified Method for Calculating Diabetic Diets. J.A.M.A., 133: 169, 1947.

Table 123. Food Exchanges

## LIST 1. MILK EXCHANGES (carbohydrate, 12 gm.; protein, 8 gm.; fat, 10 gm.; calories, 170)

	Measure	Gm.
Milk, whole*	1 cup	240
Milk, evaporated	1½ cup	120
Milk, powdered*	¼ cup	35
Buttermilk*	1 cup	240

\* Add 2 fat exchanges if fat-free.

## LIST 2. VEGETABLE EXCHANGES

A. These vegetables may be used as desired in ordinary amounts. Carbohydrates and calories negligible.

Asparagus	Lettuce
Broccoli	Mushrooms
Brussels sprouts	Beet greens
Cabbage	Chard
Cauliflower	Collard
Celery	Dandelion
Chicory	Kale
Cucumbers	Mustard
Escarole	Spinach
Eggplant	Turnip greens
	Tomatoes

B. Vegetables: 1 serving equals ½ cup equals 100 gm. (carbohydrate, 7 gm.; protein, 2 gm.; calories, 36)

Beets	Peas, green	Squash, winter
Carrots	Pumpkin	Turnip
Onions	Rutabaga	

## LIST 3. FRUIT EXCHANGES (carbohydrate, 10 gm.; calories, 40)

	Measure	Gm.
Apple	1 sm. (2" diam.)	80
Applesauce	½ cup	100
Apricots, fresh	2 medium	100
Apricots, dried	4 halves	20
Banana	½ small	50
Berries: straw., rasp., black	1 cup	150
Blueberries	¾ cup	100
Cantaloupe	¼ (6" diam.)	200
Cherries	10 large	75
Dates	2	15
Figs, fresh	2 large	50
Figs, dried	1 small	15
Grapefruit	½ small	125
Grapefruit juice	½ cup	100
Grapes	12	75
Grape juice	¼ cup	60
Honeydew melon	⅓ (7" diam.)	150
Mango	½ small	70
Orange	1 small	100
Orange juice	½ cup	100
Papaya	½ medium	100
Peach	1 medium	100
Pear	1 small	100
Pineapple	½ cup	80
Pineapple juice	⅓ cup	80
Plums	2 medium	100
Prunes, dried	2 medium	25
Raisins	2 tbsp.	15
Tangerine	1 large	100
Watermelon	1 cup	175

## LIST 4. BREAD EXCHANGES (carbohydrate, 15 gm.; protein, 2 gm.; calories, 68)

	Measure	Gm.
Bread	1 slice	25
Biscuit, roll	1 (2" diam.)	35
Muffin	1 (2" diam.)	35
Cornbread	1 (1½" cube)	35
Flour	2½ tbsp.	20
Cereal, cooked	½ cup	100
Cereal, dry (flake and puffed)	¾ cup	20
Rice, grits, cooked	½ cup	100
Spaghetti, noodles, etc., cooked	½ cup	100
Crackers, graham (2½" sq.)	2	20
Oyster	20 (½ cup)	20
Saltines (2" sq.)	5	20
Soda (2½" sq.)	3	20
Round, thin (1½" diam.)	6-8	20
Vegetables		
Beans and peas, dried, cooked (lima, navy, split pea, cow-peas, etc.)	½ cup	90
Baked beans, no pork	¼ cup	50
Corn	⅓ cup	80
Parsnips	⅔ cup	125
Potatoes, white, baked, boiled	1 (2" diam.)	100
Potatoes, white, mashed	½ cup	106
Potatoes, sweet, or yams	¼ cup	50
Sponge cake, plain	1 (1½" cube)	25
Ice cream (omit 2 fat exchanges)	½ cup	70

## LIST 5. MEAT EXCHANGES (protein, 7 gm.; fat, 5 gm.; calories, 73)

	Measure	Gm.
Meat and poultry (med. fat)	1 oz.	30
(beef, lamb, pork, liver, chicken, etc.)		
Cold cuts (4½" sq., ⅛" thick)	1 slice	45
Frankfurter	1 (8-9/lb.)	50
Fish: cod, mackerel, etc.	1 oz.	30
Salmon, tuna, crab	¼ cup	30
Oysters, shrimp, clams	5 small	45
Sardines	3 medium	30
Cheese, cheddar, American	1 oz.	30
Cottage	¼ cup	45
Egg	1	50
Peanut butter*	2 tbsp.	30

\* Limit use or adjust carbohydrate.

## LIST 6. FAT EXCHANGES (fat, 5 gm.; calories, 45)

	Measure	Gm.
Butter or margarine	1 tsp.	5
Bacon, crisp	1 slice	10
Cream, light, 20%	2 tbsp.	30
Cream, heavy, 40%	1 tbsp.	15
Cream cheese	1 tbsp.	15
French dressing	1 tbsp.	15
Mayonnaise	1 tsp.	5
Oil or cooking fat	1 tsp.	5
Nuts	6 small	10
Olives	5 small	50
Avocado	1 (4" diam.)	25

Table 124. Composition of Food Exchanges

<i>List</i>	<i>Food</i>	<i>Measures</i>	<i>Gm.</i>	<i>C</i>	<i>P</i>	<i>F</i>	<i>Cal.</i>
1	Milk exchanges	½ pint	240	12	8	10	170
2A	Vegetable exchanges	As desired	—	—	—	—	—
2B	Vegetable exchanges	½ cup	100	7	2	—	36
3	Fruit exchanges	Varies	—	10	—	—	40
4	Bread exchanges	Varies	—	15	2	—	68
5	Meat exchanges	1 oz.	30	—	7	5	73
6	Fat exchanges	1 tsp.	5	—	—	5	45

WALDO E. NELSON

# ELIMINATION DIETS (ROWE) FOR THE STUDY AND CONTROL OF FOOD ALLERGY

These diets may be modified by eliminating foods which elicit large dermal reactions or are disliked by the patient or disagree with him. They may be used before or after the failure of "test-negative diets."

The cereal-free diets exclude all cereals as well as milk, egg and other allergenic foods. Fruit-free elimination diets also exclude tomato and uncooked vegetables and fruits. The preliminary use of diet 4 is rarely satisfactory.

toms have been manifest. Thus relief for one week from symptoms occurring daily, for two weeks from symptoms recurring every two to three days, for three weeks from weekly recurring symptoms, and for three months from symptoms recurring every three to six weeks indicates that causative allergenic foods have been eliminated.

After relief has been assured, individual foods can be added, excluding any which reproduce symptoms. Each food should be taken daily for three to

Table 125. Elimination Diets

Diet 1	Diet 2	Diet 3	Diet 4
Rice	Corn, rye	Tapioca	Milk
Rice biscuit	Corn pone	White potato	Tapioca
Rice bread	Corn, rye muffin	Breads made of any combination of soy, lima, potato starch, and tapioco flours	Cane sugar
Tapioca	Rye bread, Ry-Krisp	Tomato	
Lettuce, chard	Beets, squash	Carrot	
Spinach, carrot	Asparagus, artichoke	Lima beans	
Sweet potato or yam	Chicken (no hens)	String beans	
Lamb	Bacon	Peas	
Lemon, grapefruit	Pineapple	Beef	
Pears	Peach, apricot	Bacon	
Cane sugar	Prune	Lemon	
Sesame oil, olive oil*	Cane or beet sugar	Grapefruit	
Salt	Mazola oil	Peach	
Gelatin, plain or flavored with lime or lemon	Sesame oil	Apricot	
Maple syrup or syrup made with cane sugar flavored with maple	Salt	Cane sugar	
Royal baking powder	Gelatin, plain or flavored with pineapple	Soy bean oil	
Baking soda	Karo corn syrup	Gelatin, plain	
Cream of tartar	White vinegar	Salt	
Vanilla extract	Royal baking powder	Syrup made with cane sugar	
Lemon extract	Baking soda	Cream of tartar	
	Cream of tartar	Corn starch-free baking powder	
	Vanilla extract		

Straight lines enclose foods in the cereal-free elimination diets.

\* Allergy to olive oil may occur with or without allergy to olive pollen. Mazola oil may be used if corn allergy is not present.

A minimal diet of lamb, white potato, tapioca cooked with pear and sugar, carrots, peas, pears, salt and sugar is a practical and simple one.

The patient should be given a list of allowed foods with menus and recipes and never a list of foods to avoid. Strict adherence to the diet is imperative. Allergens of foods remain in the body for more than a few days, so that dietary change must not be made until there has been an opportunity to evaluate the preceding one. The handling and odors of eliminated foods must also be avoided. Synthetic vitamins should be given as supplements to the diet.

The time necessary to maintain the elimination diets depends on the frequency with which symp-

five days before trying another. Symptoms may recur in a few minutes, hours or days according to the degree of allergy that exists.

38.....	100.4		
39.....	102.2		

To convert Centigrade readings to Fahrenheit, multiply by 1.8 and add 32. To convert Fahrenheit readings to Centigrade, subtract 32 and divide by 1.8

# Index

NOTE: In this index the expression "re" has been used to mean "in relation to." Thus "Anomalies re unexpected death" is the equivalent of "Anomalies in relation to unexpected death."

The expression "vs." denotes "differential diagnosis." Thus "Abdomen, pain, vs. pleurisy" is the equivalent of "Abdomen, pain, differential diagnosis from pleurisy."
